Success is claimed by Dr. Stanley Banks for the treatment of severe cases of diphtheria at the isolation hospital by the use of much larger doses of serum and its administration intravenously. This was described by Dr. Banks and Dr. G. McCracken in THE LANCET of July 7th, p. 4. The need for steps to be taken to prevent hospital wards being burdened with cases of bacterial diphtheria devoid of clinical signs of the disease is discussed, though Dr. Millard

thinks Leicester does not suffer as much as Birmingham or the M.A.B. hospitals in this respect.

Leeds.

Dr. J. Johnstone Jervis deplores the fall in the birth-rate, which was in 1927 the lowest ever recorded in the city's history. He has much to say against the birth control movement and in favour of large families. In discussing the housing question, however, he mentions that landlords will not accept large families as tenants, so it is to be hoped that he is able to persuade his corporation to give a preference to large families when allocating municipal houses. Since 1920 5280 houses have been built by the corporation and 5588 by private enterprise, but the list of applicants "shows very little sign of diminishing." "The poorer paid worker, of whom there is a considerable number, has not been catered for and still continues to occupy the low-rented inferior dwelling in the congested parts of the city and to crowd into houses already carrying more than their quota of occupants. It is in connexion with the housing of this class that the need to-day is most urgent." During the year some progress was made with the West-street unhealthy area, and it is hoped shortly to build houses on existing housing estates for the tenants evicted therefrom. This area only touches the fringe of the question, however, and there are many others almost as bad calling urgently for attention. The serving of notices for overcrowding is in very many instances entirely futile. At the end of the year the houses in the city numbered 121,620, of which 77,652 were back-to-back houses and 43,968 "through" houses. A table of the causes of death gives the somewhat surprising result that 3869 of the deaths occurred in the back-to-back houses and 2305 in the through houses. The first public washhouse in the city has just been opened and is a great boon, especially to the occupants of back-to-back houses. In the case of the older back-to-back houses the conveniences are trough closets and ash-pits at intervals down the street. Photographs are given showing that bedrooms may be situated over the conveniences and that the occupiers of the furthest off houses may have to walk 60 yards down the street before reaching their conveniences. The only solution appears to be the demolition of two houses in the middle of the block, so as to provide a yard for modern water-closets and ash-bins, in place of the old trough closets and ash-pits.

There is always a long list of cases awaiting admission to the Leeds General Infirmary, and a welcome addition to the hospital accommodation of the city is being made by opening the wards of the two poor-law hospitals for patients willing to pay the very moderate charges levied by the guardians. A full staff of consulting physicians, surgeons, and specialists will be available for the treatment of the patients. The maternity hospital, which last year admitted 1250 confinement cases, is to have its available beds increased to 100, and the new wards are in course of erection. In the tuberculosis scheme there has always been a shortage of beds for surgical tuberculosis. Plans are being prepared for the erection of a children's hospital with 200 beds on the Elmet Hall Estate, which will provide not only for surgical tuberculosis, but for other orthopaedic treatment and the nutritional disorders of infants. Another interesting development in the tuberculosis scheme is the taking over by the corporation of the "Factory-in-the-Field" started by the Tuberculous Ex-Service Men's Society. This will afford much needed facilities for offering men and women, disabled by pulmonary tuberculosis, remunerative employment of a suitable kind under the best conditions.

A table shows the increase in deaths from street accidents. In 1911 and 1912 there were 17 and 14 respectively, while in 1926 and 1927 there were 62 and 57. Over 90 per cent. of last year's accidents were due to motor vehicles, and the greatest increase appears to be at the age-periods 45 to 65.

Dr. Jervis thinks there has been a further decrease in the smoke pollution of the atmosphere. This may be partly due to bad trade, but chiefly to improved

stoking, the substitution of electric for steam power, and the extended use of smokeless domestic appliances. The West Riding Regional Committee has directed its attention during the year to the drafting of by-laws defining black smoke, dense smoke, and standards for smoke emission; to the introduction of smokeless appliances for cooking and heating in new buildings, and to the issue of certificates to engineers and stokers who have passed certain tests.

There are no producers of graded milk from tuberculin-tested cows. The average cow population of the city is 2188, and among them 19 tuberculous animals were found, 4 with tuberculosis of the udder, 6 with emaciation, and 9 otherwise affected. There were 59 cases of small-pox with no deaths. Ten of the cases occurred among the 4000 employees of a clothing factory. In the first case the patient had been actually at work when in the eruptive stage and with an output of 3000 suits per day it was impossible to say which garments had been handled by infected persons. There is some evidence, however, that the final steam pressing and ironing has considerable disinfecting power, the Hoffman steam press used for the cheaper garments being more efficacious in this respect than hand pressing by hot irons used for the better-class clothing. Dr. Jervis records an increase in the gonorrhoea cases attending the venereal diseases clinics, which he mentions has been observed all over the country. Coincidentally there was an increase in the notifications of ophthalmia neonatorum, 86 cases in 1927 as compared with 73 in 1926 and 50 in 1925. Dr. Jervis emphasises the need for a closer liaison in Leeds between the antenatal clinics and the V.D. clinics, so that pregnant women may secure treatment. Of the 86 cases notified in 1927, 5 of the babies died, and of the 81 survivors 4 had the sight of both eyes affected, while 2 made an imperfect and 75 a perfect recovery.

Bradford.

Dr. J. J. Buchan reports that there is much serious overcrowding, and that at the end of the year the number of applicants for new houses was approximately 2784, 658 of whom were living in apartments. During 1926 2193 new houses were erected and during 1927 2029. During 1927 1115 new municipal houses were occupied and at the close of the year 988 were in course of erection. Some progress was made during the year in demolishing buildings and clearing the site for the "White Abbey" improvement scheme. Under the Bradford Corporation Act, 1925, power is given for the compulsory removal of persons physically unable to look after their homes and this power was used in the case of an enfeebled woman of 75 years. There was a considerable increase in the work of the dental scheme as compared with previous years.

The city cows numbering 3238 undergo regular veterinary inspection and among them 16 tuberculous cows were found, of which 5 were affected with tuberculosis of the udder. The bacteriologist's report shows that 373 samples of milk were examined for tubercle and 6.4 per cent. were found to be infected. It is pointed out, however, that some of the samples were duplicated and that no definite conclusion should be drawn as to the prevalence of tuberculous infection in the milk-supply. The examination of samples of shell-fish showed that "the majority of mussels and cockles are heavily polluted," and the examination of samples of ice-cream indicated that "further control of this industry is highly desirable in the interests of public health." On the other hand, 18 samples of watercress from ten sources were all reported as "good."

Diphtheria was more prevalent than in 1926. There were 340 cases with 35 deaths—a fatality-rate of 10.3 per cent. The Schick test is not employed in the city. There were 51 notifications of small-pox with no deaths. Efforts to prevent the spread of infection were hampered by the refusal of the majority of contacts to submit to vaccination. A chart shows that the male death-rate from pulmonary tuberculosis

is always much higher than the female and was almost double in 1927.

The Bradford Corporation have powers under a local Act of 1925 for compulsory notification of venereal diseases and it is believed that these powers have not deterred persons from seeking treatment, but have operated rather in securing better treatment. The records of 1927 point to a decrease in syphilis and an increase in gonorrhœa. During 1927, with the full coöperation of the medical profession, arrangements were made for the supervision and following up of all cases of malignant or suspected malignant tumour. Midwives attended about 74 per cent. of the births and sent for medical help in 15 per cent. of their cases.

Oldham.

Dr. James B. Wilkinson reports that the orthopædic institute, generously presented by Mr. R. Greenhalgh, has done good work, especially in the light treatment of rickets. Two ladies have presented to the town a large house, which was used as a hospital during the war and which is now fitted up as a first-class nursing home. Another large house has been purchased for adaptation as a much needed municipal maternity home with 12 to 14 beds, and will shortly be ready to receive patients. During the year the scheme for the substitution of sanitary bins for ash-pits was completed. A good deal of trouble is caused by the blockage of waste water-closets, which number 24,780. At the last census there were 34,781 houses and 34,755 families or separate occupiers. The houses let in lodgings and furnished rooms are being gradually reduced in number. An unhealthy area, which is at present being dealt with, consists very largely of this type of house, and as the houses are closed the tenants are offered accommodation on the new housing site at Greenacres. Dr. Wilkinson states that in the majority of cases these tenants are trying to live up to the improved standards which their surroundings allow. Antenatal work is as yet on a small scale, the centre being attended by 104 cases, while the births numbered 2095. The stillbirths notified numbered 134, equivalent to 6.4 per cent. of the live births—a high percentage. There was a decline in the new cases of syphilis and an increase in the new cases of gonorrhœa at the V.D. clinics. There were 19 cases of small-pox in connexion with a poor-law institution. Most of the cases were in men over 60 and of a mild type, but one death of a man of 62 was attributed to the disease. Dr. Wilkinson puts forward what he calls the heretical suggestion that, in view of the enormous expense at present undertaken and of the mild type of the disease, this ailment might be treated like chicken-pox. The cases would be isolated at home and people would have the choice of escaping the disease by vaccination or of contracting it.

EAST SUFFOLK AND IPSWICH HOSPITAL.—A new pathological department was opened by Princess Mary (Viscountess Lascelles) on Oct. 20th. The site upon which the new block is erected is at the north-east corner of the hospital property. The laboratory actually stands on the site of the stables and the coach-houses of Waveney House—the house which has been reconstructed and adapted as a residence for the pathologist. The ground floor is devoted to a museum for pathological specimens, a consulting-room, a waiting-room for patients, lavatories for the staff and for patients, and a store-room. There are also outside offices and accommodation for carrying on serological and inoculation investigations. The first floor is divided into five rooms and offices. The general laboratory—a room measuring 30 feet by 18 feet—is so constructed as to obtain cross light and ventilation; a portion of the room partitioned off in plate glass will be used as a vaccine preparation room. Autoclave and sterilising rooms are provided adjoining the section cutting department. A biochemical laboratory and a dark room specially fitted for photographic work in connexion with the pathological specimens complete the block. Dr. Eric Biddle, who is in charge of the department, has been granted a sum sufficient to enable him to instal modern apparatus of the best workmanship, and it is considered that the equipment will enable the laboratory to deal with all the work which may be reasonably required, not only by the hospital itself but by private practitioners and local authorities in the area served by the hospital.

Correspondence.

"Audi alteram partem."

VACCINATION REFORM.

To the Editor of THE LANCET.

SIR,—The whole argument in Dr. Carr's able letter in your last issue is vitiated by his continued refusal to face the probability of the future reintroduction of severe small-pox into this country, or the reversion of the present mild to a severe type, as I showed in my last letter, has repeatedly occurred recently in America, although he admits the possibility of these occurrences. He is also wise in admitting the very slight danger of vaccination, for this was also proved by the recent Rolleston Committee Report in which it was shown (1) that after a minute inquiry into the allegations of the antivaccinists the Royal Commission on Vaccination of 1889-96 concluded, regarding the ill-effects of the measure, "when considered in relation to the extent of vaccination work done they are insignificant"; (2) the very few deaths following, but by no means necessarily due to, vaccination have been reduced in recent years to one-third of the former "insignificant" rate; and (3) the nervous sequelæ Dr. Carr deplors nearly all occur in primary vaccinations *after infancy*, so are mainly due to the neglect of primary infantile vaccination, and an argument in favour of increasing, not decreasing, the relatively safe and more convenient vaccination during the first year of life. If we are to abandon every advance in medical science, including vaccination, because it is occasionally attended by ill-results, we shall have to revert to the safe, if vain, uncivilised method of wearing charms as a protection against disease and death.

I welcome Dr. Carr's mention of the "mild" small-pox outbreak in Gloucester in 1923, as it enables me to point out that with upwards of 500 patients each "mild" case cost the city £200, and the loss of local trade was estimated at £20,000 a week. With between 10,000 and 15,000 cases yearly during the last three years in England and Wales the total preventable waste of public money must amount to a far larger sum than the country can afford. As Dr. Carr admits that isolation and vaccination of contacts, through a costly agency not required in well-vaccinated Germany, is necessary to control each "mild" small-pox, this burden will increase greatly with the further neglect of primary vaccination he advocates. I showed early this year that the disease has increased 66-fold in six years in this country, and last winter three times as many counties were affected as in the previous year, while the last two weeks' returns show an ominous commencement of the usual winter rise with an increase from 94 to 162 cases; so with the continued spread of the disease, most people will have to be vaccinated sooner or later, and some employers of labour have recently found to their cost that the only insurance against serious business losses due to "mild" small-pox is to employ only vaccinated persons. Is it not, therefore, wiser to close the stable door before the horse is stolen?

Lastly, the interesting suggestion of the Rolleston report to use the milder American multiple puncture method of vaccination will doubtless receive the careful consideration of the public health authorities, although its weak point is that we do not yet know for how long it affords protection, but it does indicate the right solution of the problem. This in my humble opinion is not to bank on Dr. Carr's assurance that we have nothing to fear in future from severe small-pox in this country, and consequently we should at once throw away our one sure weapon against this relentless foe, just because at the present time his attacks are individually much weakened, although he is numerically far stronger. On the contrary, I

confidently submit to the medical profession the policy of maintaining unimpaired our well-trying defences of primary infantile vaccination, supplemented during small-pox outbreaks by revaccination; and at the same time press forward the researches of the scientific workers of the Rolleston Committee with a view to eliminating any remaining inconveniences and ill-effects of primary vaccination. For my own part I am content to leave it at that.

I am, Sir, yours faithfully,

LEONARD ROGERS, Lt.-Col. I.M.S. (Retd.).

South Hampstead, N.W., Oct. 28th, 1928.

HEART FAILURE IN BERI-BERI.

To the Editor of THE LANCET.

SIR,—This is to thank you for publishing Prof. K. F. Wenckebach's lecture on Heart and Circulation in a Tropical Avitaminosis (Beri-beri) in your issue of August 11th last. By the practical method of “trial and error” I have found that, as a result of treating some hundreds of cases, heart stimulation with digitalis is worse than useless in cases of beri-beri. Though beri-beri is most common among eaters of polished rice, one of the worst cases treated was a European who lived for over a month on tinned food whilst on a surveying journey. The water-retention hypothesis is strongly borne out by the fact that large doses of magnesium sulphate given daily are very beneficial to beri-beri patients. This in conjunction with ordinary yeast as used by most cooks in the tropics for breadmaking, in one ounce doses three times a day, and a diet including green peas (*katjang idjoe*) mixed with the rice, and other foods containing vitamin B, such as marmite, will render a beri-beri case physically fit for work within three weeks. To deprive a Chinese of rice makes him miserable, but if “katjang” is mixed with it he is contented. Where freshly made yeast is not obtainable, dry yeast spores in the form of pills may be given with benefit, up to about grs. 30 daily.

Till this form of treatment was adopted beri-beri cases often remained in hospital for two or three months, instead of the two or three weeks now required. A dynamometer is useful as an index of progress. On admission a beri-beri patient usually cannot exceed a grip pressure of 30 kg., and at the end of a fortnight under yeast treatment from 60 to 80 kg. may usually be registered.

I am, Sir, yours faithfully,

A. S. TUXFORD.

Central Hospital, Lahad Datu, B. N. Borneo, Sept. 19th, 1928.

“HYPERVITAMINOSIS.”

To the Editor of THE LANCET.

SIR,—The letter of Mr. L. J. Harris and Mr. T. Moore in your last issue and your annotation of the previous week (p. 827) seem to me to raise questions of some practical as well as scientific importance.

From some work which has been carried out in this laboratory, it appears that the deleterious influence of irradiated ergosterol in excessive doses is not entirely due to vitamin D itself, since the toxic effect is not proportional to the antirachitic activity.

In these experiments, some of which are still in process, I find that young rats given a complete synthetic diet similar to that described by Drummond and Watson (*Analyst*, June, 1922) in which is incorporated ergosterol, irradiated in a non-volatile solvent, to the extent of 0.1 per cent. fail to grow, and die after about two months; similar results are obtained with 0.05 per cent., but 0.025 per cent. permits of almost normal growth. Older, but still growing, rats also respond to the diet containing 0.1 per cent. with cessation of growth. Incorporation of 0.1 per cent. non-irradiated ergosterol does not delay growth, or only to a slight extent. These results in general confirm those obtained by Mr. Harris and Mr. Moore.

With 0.025 per cent. irradiated ergosterol present in the diet the number of antirachitic “units” (K. H. Coward, *Quart. Jour. Pharmacy*, 1928, i., 27) supplied per 100 g. diet, as determined by separate experiments, is about 200,000. The amount of vitamin D consumed per diem is, therefore, about 10,000 times greater than that necessary to prevent rickets in this animal.

In contrast to the relative harmlessness of these large doses of this material, it has been found that ergosterol, irradiated under different conditions and necessarily submitted to further manipulation, may have much greater deleterious effects, although the antirachitic activity may be less than one-twentieth of that of the irradiated ergosterol used in the other series of experiments. Young rats on such a diet die within a week or so; older rats show a marked loss of weight, from which, however, recovery can ensue if the intake of the excessive amount of ergosterol be stopped.

Two inferences may be drawn, in my opinion, from the work published on D-hypervitaminosis: first, that preparations containing this vitamin should be standardised in terms of some stable standard preparation, such as that used by Dr. Coward (*loc. cit.*); and, secondly, that the deleterious effects described are produced by doses so enormous that the clinician need not fear the production of toxic effects from the administration of therapeutic doses of ergosterol properly irradiated. After all, many articles of diet are injurious when taken in excess; usually from the mere nature of the foodstuff it is impossible to consume more than a slight excess, and it is only with the concentration of essential elements in highly active forms that any danger of over-consumption can arise; but it would seem to be about as wise to restrict the use of irradiated ergosterol from fear of harmful effects as to give up the use of common salt because of its unpleasant effects when taken in excess.

Accurate standardisation of vitamin D activity, of course, will prevent not only the administration of too large a dose in error, but also that of too small a dose with the resulting failure of therapeutic effect.

I am, Sir, yours faithfully,

S. W. F. UNDERHILL, M.A., B.M., B.Ch.,

Director, Physiological Laboratories,
The British Drug Houses Limited.

London, N., Oct. 30th, 1928.

TESTING FOR COLOUR-BLINDNESS.

To the Editor of THE LANCET.

SIR,—I have been greatly annoyed to find my name on caricatures of my lantern. One lantern had actually a yellow glass labelled purple. All authorised lanterns are accompanied by a certificate signed by me stating that they are correct. I understand that a number of unauthorised “Edridge-Green lanterns” are being used in India.

Indian papers please copy.

I am, Sir, yours faithfully,

F. W. EDRIDGE-GREEN.

Walm-lane, Willesden-green, N.W., Oct. 28th, 1928.

WELFARE WORK AND THE PRACTITIONER

To the Editor of THE LANCET.

SIR,—In reply to your correspondents “Algy” and “C. D.” may I submit that in a school medical service and in an infant welfare service respectively, controlled by a common-sense perspective, the circumstances described in these two letters could not arise.—I am, Sir, yours faithfully,

R. J. MAULE HORNE,

Medical Officer of Health, School Medical Officer
M.O. in charge Child Welfare,
Poole, Dorset.

Oct. 27th, 1928.

Obituary.

SIR CHARLES SISSMORE TOMES, L.D.S.,
F.R.C.S. ENG., LL.D., F.R.S.

THE death of Sir Charles Tomes, which took place at Aylsham, Norfolk, on Oct. 24th, closes a period of more than three-quarters of a century during which the name of Tomes has been honoured by dental practitioners, not only in this country, but the world over. Sir John Tomes, who commenced the study of dentistry as a pupil of T. Fairley Smith nearly a hundred years ago, was one of the founders of modern dentistry, and the names of Tomes, father and son, will stand along with that of Pierre Fauchard in the dental surgeons' roll of honour.

Charles Sissmore Tomes was born in London on June 6th, 1846, and went to school at Radley, where

SIR CHARLES TOMES, F.R.S.

he distinguished himself at rowing as well as in other ways. Following in his father's footsteps he entered Christ Church, Oxford, as a commoner, and in 1866 took the only first-class of his year in the Natural Science School. From Oxford he went on to the Middlesex Hospital where his father was then surgeon-dentist, qualifying M.R.C.S. and L.D.S. in 1869. At that time histology was practically a new subject and inspired by Charles Robertson, his Oxford teacher, Tomes

began to devote his spare time to research, chiefly histological, the results of which, published for the most part in the Philosophical Transactions, led to his being elected a Fellow of the Royal Society at the early age of 32. It was in the same critical spirit that he approached problems more intimately connected with his daily work, and his observations and laboratory experiments disclosed facts of great value which are to be found recorded in dental journals, sometimes as papers, more often as contributions to discussions. Other workers sought his help and his work proved an incentive to such followers as the late Howard Mumery. Tomes was early appointed lecturer on dental anatomy to the (Royal) Dental Hospital of London, and his lectures were embodied in a Manual of Dental Anatomy which passed through many editions and was for long a standard work. He examined in dental surgery at the College of Surgeons for 14 years.

For many years Charles Tomes practised as a surgeon-dentist in Cavendish-square, at first with his father and later with Mr. E. G. Betts and Sir Harry Baldwin. Although too fully occupied to take an active part in political matters, his opinion was often sought concerning them. His mind was indeed more fitted to the giving of considered judgments—often of great value—than to taking part in public discussion, although he was keenly interested in all that concerned the welfare of his profession, and presided for a time over the British Dental Association. His appointment in 1898 to the General Medical Council,

as a Crown nominee, was very welcome to his fellow practitioners who previously were unrepresented on the Council, though subject to its jurisdiction. He gained the confidence and friendship of members of the Council and was elected a treasurer in 1904, holding this office until his resignation from the Council in 1920, having been granted a knighthood the year previously. During his period of office the Council moved from the old offices in Oxford-street to its own building in Hallam-street, a change involving financial responsibility which fell largely on the Council's treasurer. Tomes also served as chairman of the Dental Committee. The knowledge gained from this work was of great value to the Dentists Act Committee appointed by the Privy Council to consider what changes, if any, were desirable in the Dentists Act of 1878, the report of which Committee led to the Dentists Act of 1921.

During the war Sir Charles Tomes served as chairman of the Norfolk and Norwich Hospital and inspected for the Norfolk Red Cross. After his retirement to Norfolk at the early age of 50 he continued his scientific studies until a heart attack two years ago limited his activities. He bore without complaining the loss of an eye through accident.

We are indebted to Sir Harry Baldwin for a very interesting series of personal recollections of his friend and partner, of which the following is an extract:—

My first sight of him, Sir Harry writes, as he walked into the theatre to give his 8 A.M. lecture at the Dental Hospital, remains sharply defined in my memory; the tall, athletic figure, the striking face, the head pushed forward, the beard hanging free. I was a young student then; he was 35. His lectures on his favourite subject—dental anatomy, human and comparative—were always fully attended and listened to with the greatest attention. Before coming to London as a dental student I had made some acquaintance with the literary works of both John and Charles Tomes and was impressed by their consummate literary style, and formed the conclusion early that the two men were the leading lights of the profession I was to follow. Imagine my delight when two years later the Dean informed me that Mr. Charles Tomes desired me to join him in practice. His practice was large and chiefly of a very distinguished class. For nine and a half months of the year he slaved from morning till night with a bare half-hour's interval for lunch, and often I returned after dinner to find him pursuing some problem of practical operative work, indulging his artistic abilities by enamelling some jewellery of his own making, or fashioning a silver plaque. His eye for form and colour and his love of art enabled him to paint and sketch exceedingly well, and on several occasions his works were hanging very near the line in the Royal Academy and other London exhibitions. In both oil and water-colour he was equally successful. His many-sided mind enabled him to practise good music and to read it at sight. He used to get much pleasure out of part-singing and sang regularly as a member of the Moray Minstrels. His other recreations included boat-sailing single-handed, fly-fishing, shooting, billiards, and whist. He was a great lover of animals: he often paid visits to the Gardens (he was vice-president of the Zoological Society), and at one time performed autopsies on all the animals whose bodies he could secure. He was on very good terms with many of these during life, particularly the less harmful snakes who loved to explore his pockets. He was devoted to his own dogs, particularly Irish Setters, of which he had some fine specimens. I remember him nursing almost continuously for several days and nights a favourite hound.

Charles Tomes not only possessed a brilliant intellect but his mind was absolutely just and honourable. He was rather shy and retiring, with no desire for self-advertisement and with a positive repulsion to anything savouring of sentimentality or affectation. Whenever he purposed to make any change which might affect the interests of his

subordinates he would call them together and lay his plans before them prior to taking action. His breadth of vision, wisdom, and impartiality caused him often to be approached by fellow practitioners for help and guidance chiefly in settling difficulties with their colleagues, and his view of the case was, I believe, always ungrudgingly accepted as final. When questions arose concerning partnership or problems of an actuarial nature he never seemed obliged to refer to experts but simply and easily worked out the figures himself. It was this mathematical side of his intellect coupled with his breadth of judgment which was no doubt the reason for his appointment as treasurer to the General Medical Council soon after taking his seat in the Council Chamber.

His likeness to his father in mind and body was very remarkable. They had the same dignity of mind and character, the same powerful intellects and broad interests, the same devotion to science. Charles was taller and physically stronger than his father, but in later life the facial resemblance grew to be most striking. John began his work at a time when nothing had been done to build up and associate practitioners of dentistry into an organised and liberal profession. He had to forge his own position and that of his profession out of almost nothing, whereas Charles was born into a position carrying great prestige, received an exceptionally splendid education, and was backed by adequate funds. Father and son were a monumental pair. We shall never see their like again.

Sir Charles Tomes married in 1873 a daughter of Dr. Charles Cook, of Brooklyn, U.S.A., who survives him with a daughter.

LOUIS LAWRENCE CASSIDY, M.B. EDIN.,
F.R.C.S. IREL.

THE sudden death of Mr. Louis Cassidy last Saturday, as the result of a hunting accident, is deeply regretted throughout the profession in Dublin. He was 51 years

of age, and was within a few weeks of completing his term of seven years as Master of the Coombe Hospital.

LOUIS LAWRENCE CASSIDY.

professor of anatomy in the school of the Royal College of Surgeons in Ireland. Cassidy proceeded to the Fellowship of the College in 1911, and decided to devote himself to the specialty of midwifery, being appointed Assistant Master of the Coombe Hospital. His work in Dublin was interrupted by the outbreak of the war. He joined the Royal Army Medical Corps and was posted to the Salonika Expedition, with which he spent some three years. On his return to Dublin

he resumed work at his specialty, and in November, 1921, was elected Master of the Coombe Hospital. He also held the post of gynaecologist to the Royal City of Dublin Hospital, and had been for a time gynaecologist to Dr. Steevens' Hospital. He took an active part in the work of the Royal Academy of Medicine in Ireland, of which he was honorary secretary for foreign correspondence. He had also been for a term President of the Section of Obstetrics and Gynaecology.

Mr. Cassidy had studied much in continental clinics, chiefly at Vienna, and he did all he could to bring the Dublin School into touch with European progress. On his initiative a number of teachers from the continent gave courses of lectures in Dublin on several occasions. He worked hard to get endorsement for medical research in Ireland, and he was one of the principal movers in inaugurating the National Cancer Campaign (Ireland), to which he acted as honorary secretary. As Master of the Coombe he organised, in 1926, the Congress of Gynaecology, which marked the centenary celebrations of that hospital. Energetic in many movements for the advance of scientific medicine, Cassidy was content to work and move others to work without ever seeking publicity. In charitable causes he was as active as in scientific work, and few guessed the extent of his private generosity.

Of his service in Egypt and Macedonia during the war, Dr. W. G. Willoughby writes as follows: "Although a distinguished gynaecologist he with characteristic versatility became an enthusiastic sanitary officer in Macedonia, and did excellent work in the prevention of malaria. I have a photograph showing him with his Turkish labour detachment clearing a mosquito-infested stream. In helmet, shirt, and shorts, in a shade temperature of over 100° F., I found him as usual cheery and keen and regarded with affection by his men whether British or Balkans. The staff of the 31st Casualty Clearing Station at Janes will never forget his abilities as mess secretary of the C.C.S., especially in 'foraging.' In Mr. Cassidy we have lost not only a clever man but a charming companion and one of the most popular officers of the Twelfth Army Corps in Macedonia."

Mr. Cassidy leaves a widow with a son and daughter.

DUCHESS OF YORK MATERNITY CENTRE.—This centre was opened some three years ago in premises at 434, Essex-road, N., and it has become so popular with the mothers of the district that additional accommodation has been found necessary. On Oct. 29th a meeting was held at the centre, under the chairmanship of Lord Riddell, when an extension to the premises was declared open by Lady Lovat. A medical officer, a dispenser-chauveuse, a nurse, and three students live at the centre; the patients attend for antenatal care, and their confinements are conducted in their own homes by the students, the doctor and nurse paying as many visits as are considered desirable. At the opening ceremony Miss Gertrude Tuckwell and Prof. A. Louise McLroy spoke. The former alluded to the unanimity expressed by practitioners as to the importance of antenatal supervision in the task of reducing maternal mortality and morbidity, and said that a series of clinics similar to this centre, spread over the country, would be a factor in preserving maternal life and health. Prof. McLroy explained that the clinic, which was run in connexion with the Royal Free Hospital, was entirely devoted to maternal and gynaecological work, and not in any way connected with treatment of venereal disease. The women were encouraged to come as early in their pregnancy as possible, and were thoroughly overhauled. If any treatment was found to be necessary they were referred to their own doctor, or to the nearest treatment clinic, or sent to the Royal Free Hospital. A dental clinic had been established, and no less than 75 per cent. of the women attended it. Every patient was seen about a fortnight after delivery, and was advised to take her baby to one of the welfare centres in Islington; she was given a card with the history of her case to show the medical officer. An evening clinic was held at the centre for girls suffering from gynaecological conditions whose work made it difficult for them to attend hospital in the daytime. At this clinic any of the mothers requiring attention after confinement were also treated. There had been no maternal death among more than 500 patients cared for last year.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation on Oct. 27th the following degrees were conferred:—

M.D.—H. F. Brewer and Harold Wachter.

M.B., B.Chir.—R. M. Gilchrist, W. R. Ashby, and J. W. Monro.

The *Pinsent-Darwin Studentship in Mental Pathology* was founded in 1924 by the benefaction of Mrs. Pinsent and Sir Horace and Lady Darwin for the purpose of promoting research into any problem which may have a bearing on mental defects, diseases, or disorders. It is of the annual value of about £200 and is tenable for three years in the first instance. The student may be of either sex and need not be a member of the University of Cambridge. He shall engage in original research in Cambridge or elsewhere but may, subject to the consent of the managers, carry on educational or other work concurrently. Further particulars of the studentship may be obtained from the Registry of the University of Cambridge, and applications for appointment to the studentship should be made in proper form before Dec. 1st, 1928.

UNIVERSITY OF LONDON.—At a meeting of the Senate held on Oct. 24th Mr. Geoffrey Duveen's offer to make a further donation for the Travelling Studentship in Oto-Rhino-Laryngology was accepted with thanks, and regulations for the award of the studentship were adopted.

The Laura de Saliceto Studentship, of the value of £150, was awarded for 1929 to Mr. A. F. Watson, Ph.D., for the purpose of continuing investigations on a detailed study of dietary and other factors contributing to the genesis and development of experimentally induced tumours in animals.

University College Hospital.—Three lectures, illustrated by lantern slides, will be given by Dr. Charles Singer at University College Hospital Medical School, Gower-street, on Mondays, Nov. 12th, 19th, and 26th, at 4.15 p.m. The subjects will be diphtheria, small-pox, and plague respectively. The lectures will be open to all medical students of the University.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary meeting of the College was held on Oct. 25th, with the President, Sir John Ross Bradford, in the chair.

Dr. William Willis Dalziel Thomson was admitted to the Fellowship in absentia.

The following were elected Members:—

Mahomed Abdul Hamid, Samuel Berman, Bir Bhan Bhatia, Harold Livingstone Coulthard, William Hofmeyr Craib, Richard Desmond Curran, Wilfred Evans, Thomas Norman Fisher, Wilfred Fletcher Gaisford, Hugh Walker Gordon, Bruce Atlee Hunt, Samuel Levy Simpson, John Kirkpatrick Monro, Oswald Ellis Joseph Murphy, Frank Bett Parsons, Alan Meredith Richards, Thomas Frederick McNair Scott, Frederick Horace Smirk, Allan William Spence, Bernard Clive Tate, William Rayner Thrower, and Harold Frederick Wilson.

Licences to practise were conferred upon 150 candidates (including 19 women) who have passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the by-laws of the College. The following are the names and medical schools of the successful candidates:—

A. G. Adrian, Cape and St. Mary's; W. H. Allan, Guy's; V. E. N. Allen, Bristol; T. C. Baker, Cape and St. Mary's; G. N. Beeston, Charing Cross; W. A. Bellamy, St. Bart's; George Bellman, St. George's; W. L. M. Bigby and J. B. Blackley, Guy's; C. V. Bloom, London; K. C. Blyth, Sheffield and London; B. J. Bouché, Madras and Guy's; M. T. Brockman, J. D. Cambrook, and F. E. Camps, Guy's; Mohammed Sobhi Chafey, Cairo and Charing Cross; Benjamin Cimbelmann, Basle and Middlesex; H. A. Clarke, Guy's; A. M. Clarkson, Univ. Coll.; L. I. Cohen, London; S. M. Cohen, Cape and Guy's; Elizabeth Cooper, Royal Free; R. A. S. Cory, Bristol; W. W. Craner, London; T. V. L. Crichtow, King's College; H. W. D. Crook, Guy's; S. H. Croot, Cambridge and Guy's; T. M. Davie, Oxford and Middlesex; Evelyn M. Davies and H. S. Davies, King's College; C. C. Davis, Univ. Coll.; D. C. L. Derry, St. Thomas's; P. C. C. De Silva, King's College; J. S. Dinsdale, Leeds; Marjorie M. Dobson, Royal Free; Archibald Dodd, Liverpool; F. T. Doleman, St. Mary's; R. M. Dowdeswell, Cambridge and St. Thomas's; Richard Doyle, Liverpool; E. C. Duffett, Cambridge and Guy's; J. T. Dunkerley, Cambridge and St. Bart's; F. W. Earle, Liverpool; E. L. Edmondson, Cambridge and London; Dorothy E. Elington, Royal Free; H. F. Ellis, Liverpool; Mahmoud Mohamed El Toubi, Cairo and Sheffield; C. N. Evans, St. Bart's; Geraldine W. Everett, Royal Free; J. S. F. Fairley, Cambridge and Birmingham; W. B. Fieldman-Green, Cape, Oxford, and St. Mary's; R. L. Flott, Ottawa; H. T. Flint, Westminster; Agnes B. Franklyn, Royal Free and St. Mary's; G. H. V. Froxgutt, Sheffield; Maximo Gamba, Costa Rica and St. Bart's; J. H. P. Games, Univ. Coll.; Isiah Kifotos Gayid, Cairo; W. N. O.

George, Cardiff and Univ. Coll.; Reginald Glanville, Guy's; F. W. H. Grenier, Cambridge and London; Valentina Pavlovna Guercken, Westminster; H. W. Guinness, St. Bart's; F. R. Gusterson, St. Thomas's; Linnie A. Hamar, Charing Cross; W. F. L. Hannay, Guy's; W. G. Harvey, St. Mary's; C. K. Haskard, Adelaide and London; W. E. Herbert, Guy's; H. P. Himsforth, Univ. Coll.; Benjamin Hoffenberg, Cape and Liverpool; J. H. Hopper, Cambridge and St. Thomas's; Stanford Howard, Oxford and London; C. F. Howes, St. Thomas's; Maurice Hurwitz, Leeds; Esmé I. Hyam, Univ. Coll.; John Ives, St. Mary's; L. A. Joelson, Cape and London; C. H. Johnson, Guy's; D. T. Jones, Cardiff and Guy's; G. R. Jones, Cambridge and King's College; J. G. Jones, Cambridge and Univ. Coll.; Hassenjee Joomye, Middlesex; P. G. S. Kennedy, Cambridge and London; Esther M. Killick, Leeds; Simon Kin, King's College; R. W. Knowlton, Cambridge and Middlesex; T. C. Kohler, Adelaide and London; Marie Krestin, Charing Cross; Lekhraj Rochiram Lalwani, Bombay and London; A. L. Light, Leeds; T. K. S. Lyle, Cambridge and King's College; R. G. Macbeth, Oxford and King's College; A. L. McFarlane, King's College; C. M. MacGeoch, Birmingham; W. McO. MacGregor, Cambridge and London; Kundan Lall Malhaura, Punjab and Univ. Coll.; C. E. Martin, Birmingham; E. R. R. Mellon, Guy's; W. T. Mills, St. Bart's; Joseph Mindline, Westminster; A. D. Morton, Cambridge and St. Thomas's; L. H. Mottet, Univ. Coll.; E. C. Murphy and J. R. Murray, London; Edith G. Niven and Eric Ogden, Univ. Coll.; C. R. L'E. Orme, Cambridge and King's College; C. G. Paine, St. Mary's; V. E. Palmer, Cambridge and St. Thomas's; Keren I. Parkes, King's College; G. F. D. Perrott, Birmingham and St. Bart's; E. R. S. Phillips, Oxford and London; G. W. Pickering, Cambridge and St. Thomas's; P. H. L. Playfair, Cambridge and King's College; T. R. Plummer, Oxford and St. George's; E. E. Prebble, Liverpool; Norman Pycroft, Leeds; Henry Richards, Guy's; H. G. G. Robertson, St. Thomas's; R. D. Robinson, St. Bart's; R. S. Robinson, Middlesex; Margaret C. Rosser and H. W. Round, Birmingham; E. L. Rubin, Liverpool; D. J. Sagor, Cape and London; G. H. Sanderson, Cambridge and Univ. Coll.; Raghunandan Vinayak Sanzgiri, Bombay and London; J. E. Schneider, St. Thomas's; S. A. Scorer, Guy's; Elizabeth H. Scurfield, Royal Free; Mary C. Seward, Cambridge and Univ. Coll.; R. R. Shapland, Middlesex; Samuel Shone, Guy's; Maurice Silverstone, Liverpool; J. E. Snow, St. Bart's; Ernest Somasekhar, Madras and Birmingham; Venkatachari Srinivasan, Madras and Middlesex; Barry Stewart, Cambridge and Leeds; J. O. Terry, Leeds; P. R. Thambugala, Calcutta and Middlesex; A. R. Thomas, Cambridge and St. George's; C. P. K. Toland, Cambridge and Westminster; E. A. Utting, St. Mary's; H. D. Vasey, St. Thomas's; R. G. L. Waller, Westminster; David Wardrop, Birmingham and St. Mary's; Jack Wasserzweig, Cape and London; Olive C. Watkin, Charing Cross; C. E. W. Wheaton, St. Thomas's; A. P. D. Whitfield, Birmingham; L. V. Williams, Cardiff and St. Bart's; L. K. Wills, Cambridge and Guy's; Alan Wilson, Leeds; John Winter, Middlesex; F. W. J. Wood, Cambridge and St. Bart's; Margaret D. Wright, Univ. Coll.; J. M. Wrigley, Sheffield and London; Nubar Yacoubian, Birmingham; and H. S. T. Young, Cambridge and St. Thomas's.

The Streatfield Research Scholarship was awarded to Dr. R. A. Hickling, and the Jenks Memorial Scholarship to Hugh Donald Fleming, late of Epsom College.—The appointment of Dr. J. A. Glover to the Milroy Lectureship for 1930 was announced, and Mr. W. A. Greene, K.C., was elected Senior Standing Counsel to the College.—The following were elected as Councillors: Dr. C. R. Box, Dr. J. H. Thursfield, Dr. Charles Bolton, Sir Charlton Briscoe, and Dr. J. A. Arkwright.—Sir Francis Champneys was re-elected to represent the College on the Central Midwives Board.—Dr. Raymond Crawford was re-elected a member of the committee of management.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates passed in the under-mentioned subjects:—

Surgery.—G. N. Beeston, Charing Cross Hosp.; J. M. Connor, St. Mary's Hosp.; L. P. Gregory, Bristol; H. H. Jackson, Charing Cross Hosp.; E. P. Johnson, Manchester; A. A. Leibovitch, Kharkoff and London Hosp.; K. R. Lundberg, Minnesota, U.S.A.; and D. F. Michael, St. Mary's Hosp. *Medicine.*—A. R. D'Abreu, Leeds; E. A. Johnstone, Manchester and Charing Cross Hosp.; T. K. S. Lyle, King's College Hosp.; C. P. Madden, St. Bart's Hosp.; A. F. Quarumby, Birmingham; and A. E. Vawser, London Hosp. *Forensic Medicine.*—G. E. Bent, Manchester; J. M. Connor, St. Mary's Hosp.; A. R. D'Abreu, Leeds; A. E. Gibbs, London Hosp.; E. A. Johnstone, Manchester and Charing Cross Hosp.; T. K. S. Lyle, King's College Hosp.; M. H. Rashwan, Guy's Hosp.; and R. W. Scanlon, St. Thomas's Hosp.

Midwifery.—J. M. Connor, St. Mary's Hosp.; N. Das, London Hosp.; W. S. Ghal, Charing Cross Hosp.; M. Hurwitz, Leeds; E. A. Lipkin, Liverpool and Charing Cross Hosp.; E. O'C. Parsons, Sheffield and St. Bart's Hosp.; A. F. Quarumby, Birmingham; R. W. Scanlon, St. Thomas's Hosp.; and A. W. B. Wiggins, Sheffield. The Diploma of the Society was granted to the following candidates, entitling them to practise in medicine, surgery, and midwifery: A. R. D'Abreu, A. E. Gibbs, M. Hurwitz, H. H. Jackson, A. A. Leibovitch, C. P. Madden, A. F. Quarumby, and A. E. Vawser.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—At the Dental Examinations just concluded the following were the successful candidates:—

FIRST DENTAL PROFESSIONAL EXAMINATION.

Charles Purves Moore.

Biology.—Christine Evelyn Rose and Eric Thomas Jardine Dykes.

FINAL PROFESSIONAL EXAMINATION.

L.D.S. R.C.S. Edin.—Dorothy Williams, John Watson Gregory, Terence George Ward, Hamish Gordon Somerville, William James Rankine, Agnes Ferguson Miller, Peter Jackson Veitch Robertson, Duncan Gould, Owen Hartley Wicksteed, Francis Kerr Fenton, Eric Howarth Watson, William Russell Logan, Robert Allan Wilson McKendrick, and Fathi Soliman Abaza.

Pathology.—Donald McLeod Stuart.

Medicine.—George Gordon Brown and William Paterson Shand.

Surgery.—George Gordon Brown and William Paterson Shand.

Dental Subjects.—Joseph Gordon Medcalf and Mark Lessnoff.

UNIVERSITY OF MANCHESTER.—Dr. E. W. Twining has been appointed lecturer in radiology.

UNIVERSITY OF LEEDS.—The annual dinner of past and present students of the School of Medicine, Leeds, will take place on Nov. 8th at the Hotel Metropole, Leeds, under the presidency of Dr. C. W. Vining.

ROYAL INSTITUTE OF PUBLIC HEALTH.—The next annual congress of this Institute will be held in Zurich during Whitsuntide, 1929, the dates being May 15th–20th.

BRITISH INSTITUTE OF RADIOLOGY AND RONTGEN SOCIETY.—The annual dinner of the British Institute of Radiology incorporated with the Rontgen Society, will be held at the Trocadero Restaurant, Piccadilly-circus, London, on Friday, Nov. 16th, at 7.30 for 7.45 P.M. The President, Mr. G. W. C. Kaye, D.Sc., will take the chair.

BRITISH COMMITTEE ON RHEUMATISM.—A meeting to consider the reorganisation of this committee on a wider and more independent basis will be held at the house of the Royal Society of Medicine, 1, Wimpole-street, London, W., on Wednesday, Nov. 7th, at 5 P.M. Any member of the medical profession interested in this proposal is invited to attend.

GLASGOW UNIVERSITY CLUB, LONDON.—The annual autumn dinner of this club is to be held at the Trocadero Restaurant, Piccadilly-circus, on Friday, Nov. 23rd, at 7.15 for 7.30 P.M., when Mr. James Bonar, LL.D., will preside. Any Glasgow University men who, though not members of the club, would like to attend are requested to communicate with the Hon. Secretaries at 62, Harley House, N.W. 1.

POST-GRADUATE COURSE ON DISEASES OF THE CHEST.—The Joint Tuberculosis Council has arranged a course of post-graduate lectures and demonstrations on the Pathology of Tuberculosis and Allied Chest Diseases, to be given at the City of London Hospital, Victoria Park, E., from Nov. 26th to Dec. 1st. The lecturers will be Dr. S. Roodhouse Gloyne, Dr. W. Burton Wood, Dr. F. G. Chandler, Dr. Clive Riviere, Mr. R. H. O. B. Robinson, Dr. H. V. Morlock, and Dr. J. V. Sparks, and the wards and special departments of the hospital will be open to members of the course. Further information may be had from Dr. William Brand, hon. secretary of the Council, at The Larches, Farnham Royal, Bucks.

DONATIONS AND BEQUESTS.—By the will of the late Dr. J. J. Perkins, St. Thomas's Hospital Medical School will receive £1000 for research work.—The late Alderman James G. Lowe, J.P., of Stalybridge, Cheshire, left by will £1000 to the District Infirmary, Ashton-under-Lyne, for the Endowment Fund.—The Orthopaedic Hospital and Home for Crippled Children, Bristol, will benefit by the sum of £500; and the Royal Infirmary, Bristol, the General Hospital, Bristol, and the Bristol Eye Hospital by £250 each, under the will of the late Mr. F. C. Niblett, of Clifton, Bristol.—The late Miss Alice Temple, of Kingston-on-Hull, left among other bequests £500 to the Hull Royal Infirmary and £250 each to the Hull Blind Institution, the Hull and Sulcoates Dispensary, and the Victoria Children's Hospital, Hull.—The Middlesex Hospital has received from Mr. G. Vaughan Morgan a further donation of £5000 for the rebuilding fund.—St. Mary's Hospitals, Manchester, have received the following legacies: Executors of the late Sir Edward Holt, £1000; executors of the late Henry Franc, £500.—The King has forwarded £728 to the Queen's Institute of District Nursing, the proceeds of the opening of the Sandringham Gardens to the public during the season.—Mr. Charles Curd, M.R.C.S., of Bath, left £250 each to the Royal United Hospital, Bath, and the Monmouth-street Society, Bath.

NEW TREASURER OF RADCLIFFE INFIRMARY.—Mr. W. W. Goodenough, of Broadwell Manor, Lechlade, has been elected honorary treasurer of the Radcliffe Infirmary, Oxford, in succession to the Rev. G. B. Cronsaw.

ST. THOMAS'S HOSPITAL DINNER.—Mr. E. F. White took the chair at the annual dinner at St. Thomas's House on Oct. 26th. He had found records, he said, of an anniversary dinner held as long ago as 1822, and he felt sure that the custom had been going on for more than 100 years. He himself had entered the hospital in 1876 when there were many remnants of the old Surrey-gardens tradition, of which he gave some entertaining reminiscences. As an old captain of cricket and football he hoped to see St. Thomas's House filled with cups, and he would like to know where were the records of the past 50 years. When the present generation could do better than his own generation he would take off his hat to them. Mr. G. Q. Roberts referred to the scheme for transferring the medical school to the other side of the road and building an extension of the hospital where the school now stands. He also spoke of the appointment of Dr. R. J. C. Thompson to succeed Dr. L. B. Maxwell as medical secretary. Prof. L. S. Dudgeon, as Dean, said that he doubted whether the medical school had ever been in a more flourishing condition. This was especially due to the skill, enthusiasm, and devotion of Sir Cuthbert Wallace over a period of ten years, and he thought that no man had ever done more for the welfare of the hospital. After referring to the losses sustained during the past year, with special mention, among others, of Sir Bryan Donkin, Dr. Chisholm Williams, and Dr. J. J. Perkins, Prof. Dudgeon went on to speak of the knighthood conferred on Mr. Percy Sargent and of recent changes in the staff. Dr. S. J. Cowell had been elected to the new chair in dietetics; Dr. W. H. B. Stoddart was retiring to a leisure in which he would be able to think still higher thoughts; and the place of Dr. Thomas Carnwath as lecturer in public health had been taken by Dr. C. T. Maitland. A post-graduate course had been held in September and had proved a colossal success. Next year it might be held at the time of the annual dinner. After recounting the athletic honours of the year—including the winning of the golf, tennis, second XI. hockey, and the boxing for the third year in succession—and the academic distinctions, Prof. Dudgeon concluded by proposing the health of the chairman. Besides being anaesthetist to the hospital, Mr. White, he said, had been a great athlete, an international Rugby footballer—which very few anaesthetists to the hospital now were—and had taken an important part in founding the new St. Thomas's House.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Albemarle-street, W.

THURSDAY, Nov. 8th.—4.30 P.M. The following papers will be read: S. B. Schryver, F.R.S., and E. J. Candlin: Investigations on the Cell Wall Substances of Plants, &c. S. Dickinson: Experiments on the Physiology and Genetics of the Smut Fungi. (Communicated by V. H. Blackman, F.R.S.) Isabella Gordon: Some Further Studies in the Development of the Skeleton in Echinoderms. (Communicated by E. W. MacBride, F.R.S.) R. R. Gates and F. M. L. Sheffield: Chromosome Linkage in certain *Gnethera* Hybrids. (Communicated by Sir John Farmer, F.R.S.) The following papers will be read in title only: Ruth Deanesly: A Study of the Adrenal Cortex in the Mouse and its Relation to the Gonads. (Communicated by J. P. Hill, F.R.S.) W. J. Dakin: Anatomy and Phylogeny of Spondylus, with a particular reference to the Lamellibranch Nervous System. (Communicated by E. W. MacBride, F.R.S.) W. J. Dakin: The Eyes of Pecten, Spondylus, Amussium and Allied Lamellibranchs with a short discussion on their Evolution. (Communicated by E. W. MacBride, F.R.S.) C. E. Walker: Artefacts as a Guide to the Chemistry of the Cell. (Communicated by Sir John Farmer, F.R.S.) F. F. and P. Parjia: Analytic and P. Parjia: Analytic Study of the Respiration in Apples in Nitrogen and its Air. (Communicated by F. F. Blackman, F.R.S.) Respiration (3). Formulation of the Respiration of Apples and...

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, Nov. 5th.—8.30 P.M. DISEASE IN CHILDREN. A Discussion will be held on Fibrosis of Lung. Openers: Dr. L. S. T. Burrell, Mr. Tudor Edwards.

TUESDAY.—5.30 P.M. ORTHOPEDICS. (Cases at 4.30). 8.30 P.M. PATHOLOGY. Laboratory Meeting at University College Hospital Medical School.

WEDNESDAY.—5 P.M. HISTORY OF MEDICINE. The following papers will be read:—Dr. Philip Gosse: Pirate Surgeons. Mr. Percy Flemming: The Medical Aspect of the Medieval Monastery. Dr. Charles Singer: The Medical Manuscripts of Sir William Petty. 8.30 P.M. SURGERY. Presidential Address: Sir Holburt Waring: Surgical Education and Surgical Practice in the Future.

THURSDAY.—5 P.M. BALNEOLOGY. Presidential Address by Dr. G. L. Kerr Pringle. 8 P.M. NEUROLOGY. Clinical Meeting, West End Hospital for Diseases of the Nervous System, Out-patient Department, Welbeck-street, W.

FRIDAY.—5.30 P.M. CLINICAL. (Cases at 5 P.M.) Cases will be shown by Dr. C. F. T. East: (1) Case of pulsating liver. Dr. J. G. Y. Bell: (2) Case of sacro-coccygeal tumour. Mr. H. C. Edwards: (3) Case of syphilitic disease of the radius. Mr. C. P. G. Wakeley: (4) Case of recurrent dislocation of the hip, and (5) Case of clicking hip. Dr. C. Worster-Drought: (6) Case of acromegaly. Other cases will be shown. 8 P.M. OPHTHALMOLOGY. Cases will be shown. Papers: Mr. A. H. Levy: Injury of Lens Causing Alteration of Refraction. Mr. A. F. MacCallan: Ocular Manifestations of Local Sepsis.

HUNTERIAN SOCIETY:

MONDAY, Nov. 5th.—9 P.M. (in The Cutlers' Hall, Warwick-lane, E.C.). Discussion on The Doctor on the Lady. Dame Madge Kendall, Sir St. Clair Thomson, Lady Simson (Miss Lena Ashwell), Dr. Harold Dearden, and Mr. Ivor Back have promised to take part in the discussion.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.**ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.**

TUESDAY, Nov. 6th.—5 P.M. Dr. G. F. Still: History of Pediatrics to the end of the Sixteenth Century. (First FitzPatrick Lecture.)

THURSDAY.—5 P.M. (Concluding FitzPatrick Lecture.)

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Nov. 5th.—5 P.M. Mr. T. W. P. Lawrence: Demonstrations of Surgical Specimens.

THURSDAY.—5 P.M. Mr. C. H. Fagge: Axial Rotation, Purposeful and Pathological. (Bradshaw Lecture.)

UNIVERSITY COLLEGE, Gower-street, W.C.

MONDAY, Nov. 5th.—5 P.M. Prof. E. B. Verney: Urinary Secretion. (Fourth lecture.)

FRIDAY.—5 P.M. Prof. J. C. Drummond: Recent Work on Vitamins. (Fifth lecture.) 5.30 P.M. Dr. J. Owens, A.M.I.C.E.: Smoke Pollution of the Air and Public Health. (Second public lecture.)

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Nov. 5th.—10 A.M. Dr. Dowling: Skin Department. 11 A.M. Mr. Tyrrell Gray: Surgical Wards. 2 P.M. Mr. Simmonds: Surgical Out-patients.

TUESDAY.—11 A.M. Mr. Endean: Venereal Diseases (demonstration). 2 P.M. Dr. Shaw: Medical Out-patients. 2 P.M. Mr. Hamblen Thomas: Throat, Nose and Ear Department.

WEDNESDAY.—10 A.M. Dr. Burnford: Medical Wards. 2 P.M. Mr. Tyrrell Gray: Operations. 2.30 P.M. Mr. Donald Armour: Surgical Wards. 4.30 P.M. Dr. Trevor Davies: Gynaecological Diagnosis.

THURSDAY, Nov. 1st.—10 A.M. Dr. Grainger Stewart: Neurological Department. 2 P.M. Dr. Ironside: Medical Out-patients. 2 P.M. Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M. Dr. Pritchard: Medical Wards. 2 P.M. Mr. Sinclair: Surgical Out-patients. 2 P.M. Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—9 A.M. Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M. Dr. Burnford: Bacterial Therapy Department. 10 A.M. Dr. Owen: Medical Diseases of Children.

Daily, 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anaesthetic Course.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Nov. 5th.—2.30 to 5 P.M.: Medical, Surgical, and Gynaecological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.

THURSDAY, Nov. 1st.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Nov. 5th, to SATURDAY, Nov. 10th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Lecture by Mr. Aleck Bourne: When is the Retroverted Uterus a cause of Symptoms? on Mon. at 5 P.M. CHARING CROSS HOSPITAL, W.C. Clinical Demonstration in Gynaecology by Dr. Everard Williams at 2 P.M. on Wed. PRINCE OF WALES'S HOSPITAL, Tottenham, N. Clinical Demonstration in General Surgery by Mr. E. Gillespie at 3 P.M. on Fri. WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Wed. at 4 P.M., Demonstration by Dr. G. Carmichael Low on Recent work on Blood Diseases. The above are free. HAMPSTEAD GENERAL HOSPITAL, Haverstock Hill, N.W. Practitioners' Course. Second week, lectures and demonstrations in medicine, surgery and special departments. 4.30 to 6 P.M. daily. LONDON LOCK HOSPITAL, Dean street, W. Course of Clinical Demonstrations in Venereal Disease, every afternoon for four weeks.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Nov. 8th.—4 P.M., Mr. Twistington Higgins: Acute Appendicitis.

CENTRAL LONDON THROAT NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Nov. 9th.—4 P.M., Mr. J. D. McLaggan: Otosclerosis.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Nov. 6th.—5 P.M., Dr. H. W. Barber: Immunity and Anaphylaxis.

THURSDAY.—5 P.M., Dr. W. J. O'Donovan: Occupational Dermatitis.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Nov. 6th.—3.15 P.M. (at the Royal Chest Hospital) Dr. A. W. Stott: Demonstration of Cases in the Wards.

ST. PAUL'S HOSPITAL POST-GRADUATE COURSE, Endell-street, W.C.

THURSDAY, Nov. 8th.—4.30 P.M., Mr. W. K. Irwin: The Diagnosis and Treatment of Some Important Bladder Conditions.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

WEDNESDAY, Nov. 7th.—4 P.M., Dr. T. F. Cotton: Diseases of the Heart and Blood-vessels in Relation to Industrial Occupations.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Nov. 6th.—4.15 P.M., Mr. C. Roberts: Early Symptoms of Cholecystitis.

FRIDAY, Nov. 9th.—4.15 P.M., Prof. R. B. Wild: The Treatment of Patients with Inoperable Cancer.

ANCOATS HOSPITAL POST-GRADUATE LECTURES, Mill-street, Manchester.

THURSDAY, Nov. 8th.—3.45 P.M., Dr. Renshaw: Recent Advances in Medical and Surgical Antiseptics.

Appointments.

BURNET, M., M.D., C.M. Edin., has been appointed a Medical Referee under the Workmen's Compensation Act for the Central District, Sheriffdom of Perth.

CLAY, JOHN, M.B. Durh., F.R.C.S. Eng., Lecturer in Surgery in the University of Durham.

GAUNT, MARIA L., M.B., Ch.B. Leeds, Assistant Medical Officer, Leeds Maternity and Child Welfare Centre.

JONES, E. CATHERINE MORRIS, M.B., B.S. Durh., B.Hy., D.P.H., Maternity and Child Welfare Medical Officer, Gloucestershire County Council.

MARSHALL, J. L., M.B., Ch.B. Dub., Medical Officer of Markethill Dispensary District, Armagh.

MORTON, JAMES M., M.B., Ch.B. Edin., D.P.H., Assistant Medical Officer, Greenwich.

PRICHARD, A., M.D., B.Ch. Camb., Honorary Assistant Surgeon to the Ear, Nose and Throat Department, Cardiff Royal Infirmary.

TWINING, L. W., L.R.C.P. Lond., M.R.C.S., D.M.R.E. Camb., Lecturer in Radiology in the University of Manchester.

Certifying Surgeons under the Factory and Workshop Acts: ATKINSON, J. A., M.B., B.S. Lond. (Newnham, Gloucester); THOMAS, B., M.B., B.S. Lond. (Hirwaun, Glamorgan); and WEATHERHEAD, A. G. N., M.B., Ch.B. Edin. (Stretford, Lancashire).

Vacancies.

For further information refer to the adjacent second column.
Aylesford, Kent, British Legion Village, Freedom Hall.—Res.
H.P. 2100.
Birmingham City.—M.O. for Maternity and Child Welfare, £600.

Birmingham, City Babies Hospital.—Res. M.O. At rate of £150.
 Birmingham City Hospital, Little Bromwich.—Third Asst. M.O. £350.
 Birmingham, Midland Ear and Throat Hospital.—Asst. Surg. O. Also Second H.S. £200 and £150 respectively.
 Cardiff, Prince of Wales' Hospital.—H.S. £120.
 Delhi, Indian Red Cross Society.—Organising Secretary. Rs.1200 to Rs.1500 per mensem.
 Dreadnought Hospital, Greenwich.—Med. Supt. £300.
 Dumfries, Crichton Royal Mental Hospital.—Clinical Pathologist. £400.
 East Lothian, Shadwell, E.—Asst. Surg. £600.
 Exeter, M.O. £300.
 Frimley, Sanatorium.—Sen. and Jun. H.P.'s. At rate of £150 and £100 respectively.
 Golden Square, Nose and Ear Hospital, W.—H.S. £100.
 Hgh.—M.O.H. £1000.
 County Sanatorium.—Third Asst. Res. M.O. £400.
 Islington Dispensary, 303, Upper-street, N.—Asst. Res. M.O. £220.
 King's College Hospital, Denmark Hill, S.E.—Sister-Matron.
 Lahore, King Edward Medical College.—Professor of Pathology; Rs.1200-50-2100 per mensem.
 Leamington Spa, Warnford General.—H.P. and H.S. Each £165.
 L.C.C. Mental Hospitals Service.—Eighth Asst. M.O. £300.
 London Jewish Hospital, Stepney Green, E.—Hon. Asst. Phys.
 Manchester Royal Infirmary.—Res. Clin. Pathologist. £100.
 Norwich, Norfolk and Norwich Hospital.—H.S. to Ear, Nose, and Throat Department. £120. Also H.S. £120.
 Nottingham, General Hospital.—H.S. At rate of £150.
 Nottinghamshire County Council.—Tuberculosis Officer. £750.
 Portsmouth, Royal Portsmouth Hospital.—Sen. H.S. At rate of £200.
 Princess Louise Kensington Hospital for Children, N. Kensington. Hon. Asst. S. to Nose, Throat and Ear Dept.
 Queen's Hospital for Children, Hackney-road, E.—H.P., H.S., and Cas. O. Each at rate of £100.
 Reading, Royal Berkshire, Pathologist, &c. £750.
 Also Third H.S. and rate of £150.
 St. Mary's Hospital for W.—Hon. Asst. P.
 St. Peter's (Whitechapel) e-road, E.—Res. Asst. M.O. At rate of £150.
 West Bromwich, Hallam Hospital.—Res. H.S. £250.
 West London Hospital, Hammersmith-road, W.—H.P., H.S. Also Aural and Ophth H.S. Each at rate of £100.
 Windsor, King Edward VII. Hospital.—Sen. H.S. Also Jun. H.S. At rate of £120 and £100 respectively.
 Worcester General Infirmary.—Jun. Res. M.O. £120.
 Worcestershire County Council.—Asst. County M.O. £600.
 The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Prescott (Lancashire), and Huntly (Aberdeenshire).

Births, Marriages, and Deaths.

BIRTHS.

COLE.—On Oct. 26th, at 3, Wilbraham-place, S.W., the wife of Leslie Cole, M.D., M.R.C.P., of Trumpington-street, Cambridge, of a son.
 HART.—On Oct. 22nd, at Platt's-lane, N.W., the wife of S. L. Hart, L.D.S., of a daughter.
 HORNIBROOK.—On Oct. 25th, at Ethorpe House, Gerrard's Cross, the wife of H. Nevill Hornibrook, M.B., B.S. Lond., of a son.
 MATHER.—On Oct. 23rd, at Lindfield, Hayward's Heath, the wife of Dr. F. H. Mather, of a son.

DEATHS.

ABRAM.—On Oct. 24th, at Reading, Sir George Stewart Abram, J.P., M.B. Camb., in his 63rd year.
 HARTLEY.—On Oct. 21st, at Royal-avenue, Scarborough, Reginald Hartley, M.D., F.R.C.S., in his 76th year.
 KNIGHT.—On Oct. 25th, at Mecklenburgh-square, W.C., Edward Knight, M.R.C.S., late of Cook's School, in his 69th year.
 TOMES.—On Oct. 24th, at Mannington Hall, Aylsham, Sir Charles Sissmore Tomes, M.A., LL.D., F.R.S., F.R.C.S., in his 83rd year.
 WARREN.—On Oct. 23rd, at Frith Cottage, East Farleigh, Kent, John Grant Warren, L.R.C.P. & S., D.P.H.
 WETHERED.—On Oct. 28th, at his residence, Falmouth, Frank Joseph Wethered, M.D., F.R.C.P., in his 69th year.
 N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

ALCOHOL AND DRUG ADDICTION IN RELATION TO MENTAL DISORDER.*

By HUBERT J. NORMAN, M.B. EDIN.,

MEDICAL SUPERINTENDENT OF CAMBERWELL HOUSE; LECTURER IN MENTAL DISEASES AT WESTMINSTER HOSPITAL.

It is difficult to discuss this subject without becoming controversial, for it is not yet so scientifically delimited as to be free from theory and hypothesis. According to some authorities, alcohol and drugs are actually responsible for quite a large proportion of cases of mental disorder, while to others these factors are incidental and exciting rather than causative. It will be admitted that alcohol and habit-forming drugs do have a very definite influence on nervous tissue, but whether this influence is invariably deleterious is disputed. At present, however, we are dealing with those cases in which deterioration has taken place. The dire effects upon the nervous system are but one aspect of the matter. Other parts of the economy are involved, so that the deterioration may be general. Speaking at the recent Anti-Alcoholic Congress at Antwerp, Sir Arthur Newsholme said that in his view the direct and indirect deaths caused by alcoholism are under-stated at 5 per cent. (11,000) among adult males in England. Tuberculosis, syphilis, and alcoholism are probably responsible for a majority of the total male deaths occurring between adolescence and old age, and alcohol is not the least deadly of the three enemies.

Fundamental Symptoms.

Broadly considered, the effects on the cerebral cortex are, as Dercum has pointed out, the same. "Each form of intoxication is distinguished by its own special features, though in its fundamental characters it resembles every other." The variations in symptomatology appear to depend more upon the quantity of the drug and the period of time over which it is taken than upon essential differences in their effects. The chief reason for taking these substances is in order to produce euphoria. The desire may be to chase away gloom and despondency or to heighten the feeling of well-being and of competence to undertake tasks for which the individual might otherwise consider himself incapable. Indeed, it is the feeling of inadequacy which so often lies behind the excesses; or, in more fashionable language, it is an "inferiority complex" which is responsible. Usually, therefore, it is the neuropathic or unstable individual who becomes an addict or, at least, who develops morbid mental symptoms.

An interesting point is the differences of susceptibility to the effects of alcohol and drugs, even in the same individual at different times or in different circumstances. Especially important is the lowered resistance brought about by head injuries.

There seems to be little doubt that the cortex is responsible for the system of inhibitions or checks upon which the social organisation depends. Interference with these may not be accompanied by any special danger if it does not go too far. Indeed, it may be of some utility where, for example, it allows the shy and diffident person to overcome his temperamental difficulties when necessity arises. The danger lies in too frequent recourse to this assistance. Since the feeling of inadequacy is often dependent upon constitutional defect, inherent or acquired, it is easy to understand how habit-formation may occur. The weakening of inhibition may, however, go to further stages and be demonstrated by changes of conduct such as extreme boastfulness, excessive irritability, and quarrelsomeness, and even outbreaks of maniacal fury. It is only necessary to recall such conditions as amok, Berserk rage, mania à potu, and the deeds of the tribe of assassins who took hashish. Doubtless these outbursts are allied to the epileptiform attacks—or to the actual epilepsy—which occur in association with some cases of chronic alcoholism. Impulsive suicidal acts also occur. Such overactions depend upon lower ranges of cells, which are allowed to function more or less unchecked. These, being more primitive and more stable, resist the toxic influences longer, but in due course more and more of them are interfered with or put out of action and other mental changes then ensue.

Intellectual Impairment.

With these changes there may be intellectual impairment of varying degree. Although there may be lucidity there may be, on the other hand, mental confusion even to the

* A lecture delivered before the Society for the Study of Inebriety on Oct. 9th.

stage of delirium, with disorientation and disordered movements. This is a familiar result of taking alcohol: but it may be produced by other drugs, for example, chloral and chlorodyne, cocaine and heroin. These results should be borne in mind when hypnotics and sedatives are being administered in order to procure sleep. If they are not given in sufficient quantities to inhibit the action of cells other than those of the cortex, there may be increased confusion and restlessness, as during the induction stage of anaesthesia.

Association of ideas, at first stimulated, is eventually slowed down as deterioration takes place. It may be suggested that the primary stimulation is shown more in the shape of excessive imagination, even of fantastic conceptions, than as actual intellectual output. As we have become accustomed to attach an undue value to works of imagination we are apt to lose sight of their lack of real intellectual content. In this connexion may be noted frequent illogicality—or at least wayward associations—exemplifying Mr. Dooley's dictum that though alcohol may be a good thing to talk on, it is a bad thing to think on! The intellectual deterioration shows itself in other ways. There is impairment of the moral sense, so that the victims develop into liars and will do or say anything to gain their ends. There is increased egotism. The patients are untidy and careless about personal cleanliness; they are unpunctual and unreliable. They may be acquisitive even to the point of thieving. It is well to remember the importance of this from the legal point of view. The possibility of sexual derelictions is also to be noted; latent impulses emerge unchecked.

Illusions, Hallucinations, and Memory Defects.

Illusions of sight and of the other senses may occur. Numbers of stories about drink and its effects have for their basis this tendency to misinterpret sensations. These illusions depend also upon impairment of association; wrong associations are formed often with ludicrous or grotesque effects. Hallucinations are most often of sight or of hearing, and may be transient or chronic, resembling paraphrenia. Delusions are formulated in some cases. As there is apt to be suspiciousness these may take a persecutory form or, not uncommonly, false beliefs of marital infidelity. As they are accompanied by weakening of self-control, they may lead to homicidal acts. The memory is also impaired. There is defect of fixation of new memories, and also retrograde amnesia. The combination of these leads to a paucity of ideas and consequently to a general mental restriction. Hence the wearisome iteration which is characteristic of the chronic alcoholic. As there may be, in addition, paramnesia, or "false" memory, where the hiatus in recollection is filled in with imaginary details, it is easy to understand how fabrication or romancing may occur. It is often difficult to decide how much this lying is due to paramnesia or how far it is wilful perversion of the truth.

There may be aboulia, or loss of will-power, so that the individual fails to carry through schemes which he may still have the power to formulate. He finds dreaming and scheming more easy than effort. As there may also be indifference and apathy the lack of executive ability does not worry him. On the other hand, he may be conscious of his defect yet unable to overcome it. Generally, however, in cases of long standing, there is real loss of insight and of appreciation of the defects of conduct which are no noticeable to the onlooker.

Special Symptom-complexes.

Special symptom-complexes are, of course, found in association with particular substances. As alcohol is the most readily obtained, cases of mental disorder associated with it are the most familiar. The most dramatic of these is, probably, delirium tremens. The polyneuritic psychosis (Korsakow's disease) is of great interest in demonstrating that other parts of the nervous system are implicated.¹ Dipsomania is a link with the psychoses which are not dependent aetiologicaly upon drugs, for it appears to be related to, or to be a variety of, manic-depressive insanity. Epileptiform attacks in association with alcohol demonstrate, may be, the alliance with idiopathic or true epilepsy. The occurrence of alcoholic paranoia and hallucinosis inevitably suggest a relationship with ordinary paranoia and with paraphrenia.² In some instances mental disorder is the primary trouble and the taking of alcohol is only incidental, and in this connexion may be noted manic-depressive insanity, general paralysis of the insane, epilepsy, and dementia praecox. Here we have a vicious circle, and without a doubt the alcohol tends to accelerate mental

impairment. Where alcohol and other substances are taken the outbreak is still more grave.

It appears, therefore, that the taking of alcohol and other drugs, if persistent and excessive and linked, as it often is, with neuropathic defect, tends to bring the individual steadily towards the common ending of all chronic mental disorders—namely, mental impairment or even profound dementia. The minor degrees of this mental reduction may be overlooked for various reasons. For example, the chief deterioration may be in the "moral sense" and intelligence may appear unimpaired. Much greater latitude is usually allowed the individual in wickedness and depravity than in other directions. He may become a liar, or swindler, or a knave with less social reproof, maybe, than if he lets his clothes fall into disarray or forgets his table manners.

The nervous system has great potentiality for recovery even when it has been subjected for long periods to the influence of drugs. It is difficult to prophesy, even when the symptoms are very pronounced, what the results will be if the patient can be guarded against further excesses. This is, however, a very difficult matter. We are free agents in the matter of doping ourselves into a state of obfuscation, however much we may be hedged and guarded in other directions. For this reason the more stringent safeguards in the matter of dangerous drugs are very valuable. If the patient does submit to treatment in time or will refrain from further doping, recuperation may be rapid and extensive. On the other hand, cell-disintegration may have taken place, and will remain to that extent mentally crippled.

The Legal Aspect.

The matter is fairly simple when the symptoms are obvious; when there are, for example, definite aberrations of conduct, hallucinations, and delusions. But when the degree of disorder is not so marked it may be impossible to draw an arbitrary line between the "certifiables" and the "uncertifiables." It helps very little to invoke the doctrine of free-will and to say that the individuals should refrain from excess and that their disorder is their own fault. We know that a number of them are the victims of circumstances—of the "tyranny of their organisation"—and thus fated, literally and metaphorically, to fall by the wayside. It seems as if for them the only solution of the problem is prohibition. Yet a good many would come to grief anyhow, and we cannot remove all forms of temptation. However much we are dragged and made to conform to regulations it is still true that "to step aside is human." Let us continue, therefore, to heed the admonition of one who had his own sad experience and "gently scan our brother man," rather than deal harshly or unsympathetically with him.

HEALTH IN UGANDA.

In the report on Uganda for 1927, recently issued on the authority of the Colonial Office, it is stated that the activities of the Medical Department were further extended during the year. There were 480,516 new cases recorded as having attended the various Government hospitals, dispensaries, treatment centres, &c. This is an increase of 100,117 cases over the number recorded for 1926, and nearly six times the number treated in 1920. The total attendances at the various medical units numbered 2,038,448, as compared with 1,795,358 in 1926. The total number of cases admitted to wards was 21,562 and the aggregate number of in-patient days' treatment was 420,743. This gives an average daily number in wards of 1153 as against 970 in 1926. There were 3383 surgical operations performed in the year; 2127 were recorded for the previous year. Deaths in hospital showed a decrease of 286, the figures for 1927 being 1111 and for 1926 1397. This was largely accounted for by the falling off in the number of cases of dysentery during the year and the absence of a virulent epidemic form of this disease.

There are four Government European hospitals, nine Asiatic hospitals, 28 native hospitals, and 11 isolation hospitals in the Protectorate. These provide beds for 27 Europeans, 51 Asiatics, and 1391 natives. In addition there are 97 beds in isolation hospitals which may be used for either Asiatics or natives. Grants are made by Government towards the cost of medical training of both native attendants and midwives at mission hospitals and maternity training schools.

Native Vital Statistics.

Perhaps the most outstanding feature of the year from the medical point of view is the position revealed regarding the vital statistics of the general native population. The figures for the death-, birth-, and infantile mortality-rates, and the excess of births over deaths, are in all cases better than they have ever been. It would appear that they reflect the advantage which has accrued to the general native population as a result of the intensive development of the organisation for their treatment at hospitals, dispensaries, and maternity centres which has taken place during recent

¹ It occurs also in association with other substances, but most commonly with alcohol.

² It will be noted that alcohol and drugs can produce the symptoms associated with various forms of insanity. If these symptoms persist the person may be certifiably insane.

years. The first report of an excess of births over deaths in Buganda occurred in 1924 and was represented by the modest figure of 37. It was conjectured that the absence of serious epidemics was a factor in the improvement then recorded. The excess of births over deaths now reported for the five districts rendering returns is 17,000 and indicates that the position is being consolidated and that a progressive increase in the native population can now be confidently predicted. Syphilis, malaria, yaws, and ulcers are the four most common diseases of the country, in the order shown. Pneumonia, dysentery, and injuries account for the largest number of deaths in hospital. Plague and sleeping sickness required more attention than usual during the year.

The League of Nations International Sleeping Sickness Commission which assembled at Entebbe early in 1926 ceased its labours and was dissolved on June 30th, 1927. The results of the Commission's work will be of the utmost importance to African administration as well as to science. Experiments and investigations in connexion with human and animal trypanosomiasis are being actively continued at Entebbe under the direction of Dr. H. L. Duke, O.B.E., who served as chairman of the Commission, which has now been dissolved. A research institute is to be set up at Entebbe for the study of human trypanosomiasis.

Population and Climate.

For all practical purposes the Protectorate may be said to cover an area of approximately 94,204 square miles, of which 15,017 square miles is water. The population on Dec. 31st, 1927, was estimated to be 3,149,354—viz., 1867 Europeans, 11,502 Asiatics, and 3,135,985 natives. The climate of the Protectorate as a whole, though pleasant, cannot be considered healthy for Europeans. European children as a rule thrive in infancy, but considerable risk is attached to bringing them out when they are over 2 or 3 years old, as they are liable to attacks of malaria and resultant anaemia. The health of adults depends mainly on their mode of life, and, with care, constitutional health should not be impaired, but, even if physical fitness is maintained, the altitude and proximity to the Equator combine to produce nervous strain after prolonged residence. Outdoor manual labour is dangerous for Europeans, and on plantations a manager's or owner's duties are for the most part supervisory. The mean maximum temperature for most districts averages 80° F. and the mean minimum 60° F. On the Ruwenzori Range there is extreme cold with perpetual snow, and it is also cold on the higher slopes of Mount Elgon. In the Nile Valley, near Lake Albert, on the other hand, the mean maximum temperature is 90° F. and the mean minimum 74° F. The favourite localities for European plantations are the Buganda Province, the Toro district of the Western Province, and the Bunyora district of the Northern Province. Statistics taken at Entebbe give the following results: average rainfall for the last 32 years, 59.62 in.; average temperature for the last 27 years, maximum 78.7° F., minimum 62.8° F.; mean daily sunshine for 1927, 6 hrs. 12 min. The rainfall at Entebbe for the year, which was below the average, amounted to 53.73 in., distributed over 124 days.

CONFERENCE ON MATERNAL MORTALITY.

A CONFERENCE called by the Maternal Mortality Committee formed in 1927 by the initiative of Miss Gertrude Tuckwell, J.P., was held at the Central Hall, Westminster, on Oct. 30th. Lady Galway, who presided, said that the problem of maternal mortality and morbidity appealed both to emotion and to reason. It was important to collect information from social and medical workers, but it was equally important that the information should be mercilessly sifted and examined if we were not to be side-tracked. Mr. Neville Chamberlain dealt with three criticisms which had been made against the Ministry of Health. He said that (1) the Ministry had not really cut down the milk supplied to welfare centres nor instructed local authorities to reduce it; but when a reduction in expenditure had been called for from his department he had been obliged to decide between cutting down the milk grant and interfering with the development of normal health services. He had especially excluded the distressed mining areas and every local authority which was spending less than £100 a year on milk; to the rest he had been compelled to say, "You must supply what milk you think desirable, but this is all I can give from national resources." (2) Strong representations had been put forward that the National Health Insurance Act should be altered to provide medical and midwifery service before and after childbirth. An effort had been made to devise a scheme within the resources of the approved societies; it could, however, only be carried out by pooling their funds, and some of the societies refused to do this. (3) Fear had been expressed that the new system of block grants would lead to reduced help to voluntary

societies, especially those working for unmarried and their children. Though in future these societies be under the supervision of county and county councils, all grants would be considered by the Ministry would naturally have regard to what had been given past. These points were warmly contested by speakers, great disappointment being expressed that Chamberlain had not been able to wait for the discussion. Dr. Marion Phillips said the cutting of the milk grant had a discouraging effect on local authorities in other services. The sum saved was a small one, but the authorities had been told that it was a choice between this small sum and expansion of health services. Hubback pointed out that, by the block grant system the money would be paid by one cheque, no part earmarked, and there was no guarantee that a proportion would be spent on maternity and child or on health work at all. Such strong feeling was on the part of the conference that an additional resolution dealing with this point was put by Lady Galway and carried. A report covering the proposals made at conference was presented by Dr. Marion Phillips. I had shown that of the county authorities supply information asked for only 61 out of 116 carried out more than half their powers under the Maternity and Child Act. This was quite inadequate, and those who to citizen duties seriously should do all in their power to public opinion.

INSTRUCTIONS FOR PATIENTS.

THE busy practitioner might save himself much if he had ready a series of printed slips to hand to his patients explaining how to put on a fomentation, or douche, or wash the eye, and so forth. Dr. T. T. B. Watson on the idea of having such instructions printed on sheets with a perforated slip at the top which can be put in a "loose-leaf" holder. With each 25 of these a folding cover is provided, bearing on the front and inside in some cases remarks intended for the practitioner only. Having explained how a fomentation is done, the doctor reaches for his holder labelled "fomentations," and tears off a sheet to hand to the patient. The principle of the idea can be both praised and criticised. Certainly it is useful to be able to reinforce the spoken word with a printed memorandum, and as long as the matter is confined to such examples as are mentioned there is little room for differences of opinion. Other things treated in the set of eight "instructions" already more open to individual opinions. The intensive treatment of gastric and duodenal ulcer, diet in obstinate exercises for constipation, are all matters upon which there is some diversity of opinion and much room for variation in individual cases. It is, however, open to the doctor to alter such portions of the printed word as he wishes. Dr. Watson's instructions should prove extremely useful as long as the doctor is watchful of the needs of his patients, and supplements or modifies them with his own care. Messrs. H. K. Lewis and Co. publish the instructions at 25 for 1s.

"PROPYL."

Mr. W. H. Martindale sends us a bottle of "Propyl" which is a surgical antiseptic, composed of iodine and propyl alcohol, as described by Dr. R. A. Macdonald. Mr. J. Wycliffe Peck in our issue of Sept. 1st last has some serviceable features. The bottle stands firm, the aperture is semi-wide, making for quick pouring, and the stopper is of a sensible shape, excluding dust. Mr. Martindale tells us that five years ago he made a series of tinctures and spirits (described in the 19th edition of Extra Pharmacopoeia, Vol. I, pp. 122-125), which he has now replaced by "Propyl." This preparation has no objectionable odours or vapours. This is equally true of the tincture of iodine (either strong or weak) made with iso-propyl instead of ethyl alcohol.

Corrigenda.—In a leading article entitled Cardiac Lants in our issue of Oct. 20th line 20 of col. 1, p. 82, read "fall in blood pressure is not a result of cardiac

Mr. L. J. Harris and Mr. T. Moore point out that "hypercalcaemia" was misprinted "hyperglycaemia" in the footnote to their letter on "Hypervitaminosis" "Vitamin Balance," in our last issue (Oct. 27th, p. 954).

We are informed that the address by Dr. Graham to which we referred last week in an annotation on the Wisdom of Peter Harding, was delivered at the Institute of Public Health and not at the Institute of Hygiene.

Schorstein Lecture ON EXPECTORATION.

Delivered at the London Hospital on Nov. 2nd, 1928,

By CECIL WALL, D.M. OXF., F.R.C.P. LOND.,
PHYSICIAN TO THE HOSPITAL.

IN his Lumleian lectures last year Sir Charlton Briscoe¹ pointed out that the mechanical side of the respiratory mechanism has received less attention than it deserves. With this statement all those who devote special attention to diseases of the chest will be in agreement, and they will concur with him in the belief that the difficulty of the subject provides the explanation.

Briscoe combined experimental and clinical methods in a masterly manner in the endeavour to elucidate certain aspects of the subject. For many years my own work has afforded me numerous opportunities for the close clinical study of the muscular mechanism of respiration, but the problems which I have attempted to solve are different from those which he investigated, and my method has been perforce confined to the testing, by observation at the bedside, of a succession of hypotheses propounded by others or by myself. The problem which I propose to discuss to-day is that of the muscular mechanism of expectoration or, in the words of the late Dr. F. J. Smith, of the cough useful as opposed to the cough ornamental.

THE MECHANISM OF EXPECTORATION.

Expectoration is effected by raising the intrapulmonary air pressure and then suddenly allowing the air to escape and carry with it any peccant matter that may be lying in the air passages. It follows, therefore, that the requisite modification of expiration must be preceded by inspiration, and to a great extent its mechanism will be modified by the position of the thorax at the commencement of the expiratory effort. The cavity of the thorax is enlarged during inspiration partly by descent of the diaphragm, working as Halls Dally² has shown as a piston works in a cylinder, and partly by the movement of the ribs. The older view, that the action of the diaphragm is due to the flattening of its curvature, seems to be now completely abandoned. However, it must be admitted with Keith³ that, owing to the resistance of the abdominal viscera and to the situation of its attachments, the diaphragm in contracting tends not merely to lower the central tendon, but also to elevate and to some extent constrict the costal margin. This seems to be the obvious explanation of what is known as John Howard's experiment, on which Makuen⁴ apparently alone among authors, relies for his assertion that the diaphragm is an expiratory muscle. This experiment may be carried out as follows:—

The hand is placed on the epicastrum while a forcible inhalation is made, the abdominal wall being pushed forward as the diaphragm contracts. If then at the end of the maximum inspiratory effort, while the breath is held, the diaphragm is allowed to relax and the abdominal wall to recede, more air can then be inspired as the lower ribs can now move further upwards and outwards.

The constricting action of the diaphragm is also proved by the observation originally made by Gerhardt⁵ in 1860, and more recently confirmed by Pasteur,⁶ that in diaphragmatic paralysis there is an increased movement of the lower ribs.

MOVEMENT OF THE RIBS.

The movement of the ribs has been the subject of much controversy since the view expounded by Galen in the second century—that the upper intercostals, both internal and external, lifted the ribs while the lower set depressed them—was disputed by Vesalius in the sixteenth century; and the controversy is evidently not yet settled, seeing that two standard

English text-books of anatomy^{7, 8} adopt contrary views.

It is not possible for me to describe now the various views which have been held. I can but tell you the conclusions which I have reached by clinical observation. I will discuss first the movement of the ribs and then the muscles which accomplish the movement.

Keith³ pointed out that only the first ten ribs take part in thoracic respiration, the eleventh and twelfth ribs, with their single articulations to the vertebral bodies, forming part of the abdominal wall. Following Keith again, the first ten ribs may be considered to form two groups. The first group consists of the first two pairs of ribs together with the manubrium sterni; this group, he said, constituted the "operculum thoracis." The second group consists of the third to the tenth pairs with their cartilages and the gladiolus of the sternum.

The first two ribs have a double articulation with the bodies of the vertebrae and with their transverse processes, but as the transverse processes are not set back far the hinge-joints permit an up-and-down or pump-handle movement with very little if any eversion. The four articular surfaces of each pair of ribs are not in a perfectly straight line, but as Volkmann showed, if the axes of the hinge-joints were produced forwards they would include an angle of about 135°. The result of this arrangement is that the operculum thoracis moves up and down in a manner comparable with the lid of a box on its hinges.

The movement of the second group of ribs is determined by the axes of the double costo-vertebral articulations. Passing downwards the transverse processes are set progressively further back, so that, to use Volkmann's measurements again, if the axes of the hinge-joints of the pairs of ribs be produced forwards they will intersect within the chest and include angles which diminish from above downwards until the included angle is a right angle or even less (88°). Furthermore, it must be pointed out that these axes of the hinge-joints are horizontal, and if produced forwards would meet the wall of the opposite side of the chest. The bony ribs being sharply curved and sloping downwards and forwards below the horizontal the posterior upward torsion of the rib, which puzzled Hutchinson⁹ so much, seems to be a necessity.

It is admitted by all modern authorities, with the possible exception of the author of the last edition of Gray's "Anatomy," that the arrangement of these hinge-like costo-vertebral articulations only permits movement round the axis of the hinge—that the rib being curved moves like a bucket-handle and not like the handle of a pump. Hutchinson⁹ in spite of the meticulous care with which he investigated the anatomy of the thorax, did not realise this; he speaks of the ribs having two movements, the one up and down like a pump-handle, the other a movement of eversion which he thought was due to the rotation of the curved arc of the rib about its chord which he describes as joining the head with the anterior extremity. It does not appear to me to be mechanically possible for the ribs to execute the double movement, and furthermore clinical observation seems to demonstrate that it does not occur. Hamberger¹⁰ on the other hand, describes the movement correctly: "Each of the ten upper ribs," he says, "has its own fixed point on that line which can be drawn horizontally from the transverse process of the vertebra to a disc between the bodies of the two vertebrae with which the head of the rib articulates, and round this line the ribs move up and down."

If the chest of a healthy person be watched during inspiration it will be found that the body of the sternum does not swing forward markedly as it would if the ribs had a pump-handle action, but in moving upwards remains almost vertical, such movement being permitted by flexion of the angle of Louis. In certain abnormal conditions, for instance, when there is a funnel sternum or the pericardium is adherent to the sternum, the elevation of the ribs is accompanied not by an advance, but by actual recession of the

sternum. Again, if the ribs had this pump-handle movement the explanation of unilateral immobility of the thorax in pleurisy or pneumothorax would offer great difficulties.

I feel forced to adopt the view that the ribs have one movement only—that is, round the axes of their articulations with the bodies of the vertebrae and the transverse processes. The reason for the cartilages, and probably for the absence of the external interchondral muscles, seems to be found in the fact that the axes of rotation intersect within the thorax; if the anterior parts of the ribs were rigid the rotation of a pair of ribs about their axes would be mutually antagonistic, and this seems to be the case when pathological rigidity has supervened. The ribs are not horizontal, but slope downward; in inspiration they rotate upward. It is obvious that the more they slope downwards the less will be their perpendicular distance from the mid-line of the body, and the more nearly they approach the horizontal position the greater will be that distance; it is to this fact that the thoracic expansion in inspiration is due. As Luciani¹⁵ shows, the point on the convexity of the rib through which passes a tangent parallel to the axis of rotation is the point which will rise most during the upward rotation of the ribs in inspiration. The obliquity of the axis will throw this point in front of the mid-line of the axilla.

Sewall and Pollard¹⁰ claim to have demonstrated that costal respiration is more efficient than that effected by the diaphragm; over a long series of experiments measuring the vital capacity they found that if the diaphragm only was used for inspiration and expiration the average volume was 1341 c.cm., whereas if the ribs only were used the volume was 2139 c.cm. Mosso¹¹ found similarly that with thoracic respiration he inspired 2025 c.cm., whereas with abdominal respiration he inspired only 1350 c.cm.

MUSCULAR ACTION.

Great has been the controversy with regard to the movement of the ribs in respiration, but still greater and much more acrimonious has been the controversy with regard to the muscles causing the movement.

The view which seems to satisfy best my own observations is that originally expounded by Hamberger,¹² accepted with slight modifications by Hutchinson⁹ and by many others including one of the most recent authorities, Sir Charlton Briscoe.¹ This view is that ordinary quiet inspiration is effected by contraction of the external intercostals acting in concert with the interchondrals of the opposite side of the chest, the fibres of the two muscles being parallel, and that ordinary quiet expiration is an active process brought about by contraction of the internal intercostals and the *triangularis sterni* (transversus thoracis and possibly morphologically representing the internal interchondrals) and aided by gravity and the elastic recoil of the resilient chest walls.

The chief rival view was originally put forward by Aranzi, of Bologna, and van Helmont, of Amsterdam, and was recently resuscitated by Sir Arthur Keith,³ and has been adopted by the author of the last edition of Gray's "Anatomy."⁸ These authorities hold that the function of the intercostal muscles is merely passive and designed to prevent the indrawing of the intercostal spaces during inspiration. An opinion with such weighty support cannot be dismissed summarily, but my objections to it seem insuperable.

In the first place, going back as far as Hamberger and Haller, it seems to me that Hamberger's mathematical argument is sound; if two parallel rods kept parallel, move about two fixed fulcra, and two elastic bands crossing each other at an angle are fixed to the two rods, it necessarily follows that as the two rods approach to and recede from the horizontal one band will be relaxed and the other will be stretched; it is not possible for the tension on the two bands to be altered equally and in the same direction. The ribs and the crossing fibres of the intercostal muscles are comparable with such rods and bands.

Next I am in sympathy with Haller's note of doubt sounded toward the end of his attack on Hamberger: "Why should there be two sets of intercostal muscles if indeed the function of each is the same?"

Thirdly, the experiment of Newell Martin,¹² which showed that the external intercostals contract synchronously with the diaphragm and the internal intercostals alternately, is not to be explained, as Keith suggests, as a result of the injury to the animal. Newell Martin was not an amateur or inexperienced investigator, and he found that the contractions synchronised or alternated with the contractions of the diaphragm and were not irregular, as would have been the case if injury were responsible. Furthermore, we find in the wards that lesions of the lower cervical cord which lead to paralysis of the intercostal nerves are associated with cessation of costal respiration, ventilation of the lungs being maintained by the action of the diaphragm.

Finally, if the intercostal muscles are not responsible for the movement of the ribs it becomes necessary to discover how they are moved.

The exponents of the passive theory do not specify the muscles concerned with costal respiration if the intercostals do not act. Muscles passing from the shoulder-girdle would be of but little value unless the shoulder-girdle were fixed. Therefore they must assume that the muscles passing from the spine or skull to the thoracic cage perform the function—e.g., scalenes, sternomastoids, levatores costarum. Keith agrees that the levatores costarum are lateral flexors of the spine and not important elevators of the ribs. It is not possible to investigate their activity clinically; but the scalenes and sternomastoids are accessible, and clinical observation gives frequent opportunities for investigating their contraction; with the finger in the suprascapular fossa or placed over the sternomastoid their contraction can be felt easily when the chest is rigid or in the full inspiratory position. For instance, when the thorax is raised during an attack of spasmodic asthma or in spontaneous pneumothorax, the activity of these muscles during inspiration is easily demonstrable, but unless there is unusual effort caused by some such condition as I have described evidence of their contraction is not forthcoming.

If the thorax can move freely even extraordinary inspiration does not seem to call into play the scalenes or sternomastoids; but when the chest is partly handicapped, as in an asthmatic between paroxysms, then an extra inspiratory effort may be found to call into action the extraordinary muscles of inspiration. In such cases, too, during inspiration we may feel the lumbar muscles contracting presumably to fix the lower ribs so as to give the diaphragm a fixed point on which to pull.

The arguments in favour of the external intercostals being the chief muscles of ordinary inspiration strongly favour the view that the internal intercostals and the *triangularis sterni* are the chief agents in ordinary expiration. Keith³ has pointed out the improbability of expiration being merely the result of gravity and elastic recoil, and his view is in accord with the modern idea of the synergic action of muscles.

Expiration is much more closely under voluntary control than is inspiration. Speaking, singing, sneezing, coughing, are expiratory acts largely determined by the will, and it is possible by careful observation to arrive at some conclusion with regard to the muscles involved.

EXPIRATION.

Setting aside as fanciful Makuen's⁴ idea that the diaphragm may have an expiratory function, we may consider how the diminution in the volume of the thorax is brought about. Elastic recoil and gravity undoubtedly play a part, but as expiration is not obviously hampered in a healthy person by inversion there must be other forces at work. Muscles other than the internal intercostals which by their contraction can depress the ribs and contract the thorax are superficial and their contraction can be felt. In ordinary expiration evidence of such contraction,

except perhaps in the case of the transversalis, is not forthcoming. It seems, therefore, fair to assume that the internal intercostals and triangularis sterni are the muscles chiefly concerned with quiet expiration.

Expiration has much more power than inspiration. Hutchinson⁹ measured this in inches of water.

Inspiration.				Expiration.			
1.5	..	..	Weak.	..	..	2.0	..
2.0	..	..	Ordinary.	..	..	2.5	..
2.5	..	..	Strong.	..	..	3.0	..
3.0	..	..	Very strong.	..	..	3.5	..
4.0	..	..	Remarkable.	..	..	4.5	..
5.0	..	..	Very remarkable.	..	..	5.0	..
6.0	..	..	Extraordinary.	..	..	6.0	..
7.0	..	..	Very extraordinary.	..	..	10.0	..

In forced expiration many muscles are called into play. The transversalis acts partly by compressing the abdominal viscera and so forcing the diaphragm upwards and partly by constricting the lower outlet of the thorax. When extra effort is required—for instance, in the act of coughing—all the muscles passing between the pelvis and thorax may be called into action. Of these the most important appear to be the recti and obliques together with the ilio-costalis and the pelvic portion of the latissimus dorsi, the contraction of which can often be seen and felt with the greatest ease. In extraordinary expiratory effort not merely is the thoracic outlet constricted, the diaphragm driven up, and the ribs depressed, but there is in addition a flexion of the thoracic and cervical spine to aid the depression of the ribs.

CLINICAL APPLICATIONS.

This study of the muscular mechanism of expiration would have but little clinical value unless it were possible to make a practical application in the treatment of disease.

One of the simplest applications of our knowledge may be found in the dietetic treatment of chronic bronchitis or a tendency to recurrent bronchitis in a patient with abdominal obesity. The reduction of his girth will in many ways assist in the descent of the ribs and constriction of the thoracic outlet and so permit easy and beneficent expectoration. Another application may be found in the treatment of active hæmoptysis. Not infrequently in this condition we find the patient kept lying flat; in this position he is unable to cough and expectorate easily, and as a result with each gush of blood he starts up in bed and leans forward in order to get rid of it. This movement cannot be beneficial. It is far better to allow the patient to be in a semi-sitting position so that expectoration may be accomplished with the least effort. In addition, the effect of gravity in lowering the pulmonary blood pressure is probably advantageous by promoting clotting. Concomitant fainting may not be a disadvantage.

In the treatment of all kinds of cough associated with expectoration it is an advantage to allow the patient to sit so as to fix the pelvis and to bend the spine and neck forward so as to aid the depression of the ribs. If there is inspiratory difficulty at the same time the patient should lean on something firm so as to fix the shoulder-girdle and give the muscles of extraordinary inspiration a fixed point from which to act. The child with pertussis likes its mother to hold its head during the inspiratory whoop.

OPERATIVE MEASURES.

Within the last few years the method of paralyzing one-half of the diaphragm by evulsion of the phrenic nerve has been used in the treatment of diseases of the lung. This operation has the effect of permitting partial collapse of the lung, the dome of the paralysed half reaching as high as the fourth or even the third costal cartilage as shown by radiography. During inspiration the failure of the diaphragm to descend checks the expansion of the apex of the corresponding lung while the costal movement still secures the expansion of the lower part and is to some extent facilitated by removal of an antagonistic force; the rest thus secured to the affected apex seems to explain the benefit following the operation in certain autotoxic cases of pulmonary tuberculosis.

It is not always sufficiently realised that the descent of the diaphragm is the chief cause of the expansion of the apex of the lung; radiographers are emphatic on this point, and perhaps it is due to this that the abdominal-breathing male is more commonly attacked by tuberculosis than the costal-breathing female.

Expiration is also modified by diaphragmatic paralysis. In the ordinary movements of quiet respiration there is not much difference to be noted, but with forced expiration—for instance, in coughing—the effect of abdominal constriction seems to be markedly enhanced, and to this seems attributable the benefit resulting from evulsion of the phrenic in basal bronchiectasis. In this condition the rise in the level of the diaphragm is not likely to lead to collapse of the thickened and rigid bronchial tubes, and in the majority of cases there is not much aerated lung tissue left. The undoubted improvement which frequently follows the operation must be attributed to the greater ease of expectoration which prevents the stagnation and decomposition of the secretions in the dilated tubes. The quantity of sputum may not be greatly diminished, but usually there is an early and marked reduction in the sputum.

The operation of evulsion of the phrenic should be undertaken only after careful investigation of the muscular movements of respiration in the individual patient. If there is any difficulty in costal respiration paralysis of the diaphragm is likely to have serious results. A raised and rigid chest with respiration totally of the abdominal type would be an obvious contra-indication, but it seems necessary to exercise the greatest caution if the patient has to use such muscles as the scalenes in ordinary inspiration, and even if he calls them into action when taking a deep breath. I feel that this word of warning is necessary in spite of Lange's¹⁴ statement that in elderly people, in whom diaphragmatic breathing more or less predominates, phrenicotomy does not lead to respiratory embarrassment.

THE RAISED AND RIGID CHEST.

How to aid the mechanism of coughing and expectoration when the chest is raised and rigid is a problem which is most difficult of solution. It is not infrequently held that the thorax becomes rigid owing to calcification of the costal cartilages. A study of radiograms of the chest shows that this is certainly not a complete explanation. The chest may be raised and rigid though there is no evidence of calcification; on the other hand, marked calcification is sometimes found in quite young persons whose costal movements are free. The chest may be raised and the ribs nearly horizontal, as in the so-called "artilleryman's chest" and in the child before puberty without any evidence of rigidity, and sometimes the chest may be rigid and moving as a whole, though the ribs are depressed and sloping. Sometimes—for instance, during an attack of spasmodic asthma—the raising of the chest and the inhibition of costal movement is only temporary, and again costal respiration may become impossible owing to some lesion of the lower cervical or upper dorsal region of the cord.

At times one is tempted to seek the cause of thoracic rigidity in some lesion of the costovertebral articulations, but unless there is evidence of spondylitis logical support of the speculation is seldom forthcoming. In all such conditions, however, a knowledge of the mechanism of expectoration may be of great assistance in reducing the discomfort of the patient.

THE ULTIMATE RESULTS OF QUINIDINE THERAPY IN AURICULAR FIBRILLATION.

By J. CRIGHTON BRAMWELL,* M.A. CAMB.,
M.D. MANCH., M.R.C.P. LOND.,

ASSISTANT PHYSICIAN TO THE MANCHESTER ROYAL INFIRMARY;
AND

REGINALD ELLIS,* M.B. MANCH.,
REGISTRAR TO THE CARDIOGRAPHIC DEPARTMENT OF THE
INFIRMARY.

THE observations of those who first used quinidine in the treatment of auricular fibrillation showed that normal rhythm could be restored in at least 50 per cent. of the cases treated. Soon, however, it became apparent that it was only in a much smaller number that normal rhythm was maintained. Some patients revert almost immediately to fibrillation, while others in whom sinus rhythm has persisted for weeks, months, or even years, eventually relapse. The mere restoration of normal rhythm is therefore no criterion of the value of quinidine as a practical therapeutic agent; and whether this drug will still be regarded as a useful remedy in years to come depends, not on its capacity to convert fibrillation to normal rhythm, but rather on considerations such as (1) the percentage of cases in which normal rhythm is more than a merely transient event, (2) the benefit which accrues from the restoration of normal rhythm, and (3) the dangers incidental to the use of quinidine. The sudden appearance of heart failure which frequently accompanies the onset of fibrillation is due, in part at least, to the increased heart rate. This can often be controlled by digitalis. So if quinidine is to "win its spurs" in the field of practical therapeutics, it must be shown that the condition of the patient in whom normal rhythm has been restored by its use is at least as good, if not better, than that of his fellow sufferer in whom the ventricular rate is held in check by digitalis.

Method of Investigation.

With a view to ascertaining the ultimate results of quinidine therapy we have followed up the after-histories of an unselected † group of patients treated with the drug in the Manchester Royal Infirmary during the past six years. When we first began to use quinidine we were groping in the dark, for we did not know in what type of case the drug was most likely to prove beneficial. Consequently, in the light of further experience, we should now regard some of our earlier cases as unsuitable, and would prefer to treat them with digitalis. Nevertheless it is instructive to consider the effects of quinidine in these cases, even if merely to emphasise the importance of judicious selection.

* Working for the Medical Research Council.

† All patients in whom treatment was controlled electro-cardiographically have been included.

Chronic, as opposed to paroxysmal, auricular fibrillation is especially liable to occur in association with three pathogenic processes: (1) rheumatic infection of long standing, (2) degenerative myocardial fibrosis, and (3) thyroid intoxication. To the last of these we do not propose to refer in this paper, for the observations of F. R. Fraser⁵ and his co-workers have shown that in this type of case normal rhythm can easily be restored and maintained, provided the source of the underlying toxæmia be first removed by adequate surgical measures, whereas, so long as hyperthyroidism persists, there is a strong tendency to relapse. Our own observations entirely corroborate Fraser's views.

It is not always easy to determine with certainty the ætiological factor in chronic fibrillation. The recognition of the thyrotoxic cases rarely presents much difficulty, but the hearsay evidence of supposed rheumatic infection is often unconvincing. Putting on one side the cases with a clear history of heart trouble dating from an attack of rheumatic fever or chorea in childhood, there remain those in which the signs of heart disease were first noticed in early adult life. These patients may, or may not, give a definite history of acute or subacute rheumatism. Some have mitral stenosis, while in others auscultation fails to reveal any sign of a valvular lesion. For the purpose of the present investigation we have regarded these cases as probably rheumatic, though we are bound to admit that the evidence on which the diagnosis rests is not always conclusive. Similarly, we have classified as "fibrotic" those in whom the cardiac symptoms appeared insidiously during the degenerative period of life.

Since our object is to ascertain what eventually happens to these patients, we have excluded from this survey all those who first came under treatment within the past two years. This leaves us with 27 cases, all of which have now been kept under observation continuously, so long as their rhythm remained normal—that is, say, for varying periods up to five years. We arbitrarily selected the period of two years, in the hope that by the end of that time the cardiac mechanism would have become sufficiently stable to afford a reliable guide to the more remote prognosis.

In the title of this paper we have used the words "ultimate results of quinidine therapy." To have done so is perhaps misleading, for the term ultimate suggests finality, and should therefore strictly be employed only in the case of those patients whose after-histories have been followed up to the time of their death. Our reason for choosing this title was to indicate that we were concerned not with the immediate, but with the more remote results of treatment, and we have included not only those patients who have died, but also those who are still living.

Classification of Results.

The classification adopted requires a word of explanation. We have divided our cases into two groups—"successful" and "unsuccessful." Each of these groups has again been subdivided. The successful group includes those patients who derived definite benefit for a considerable period of time from the restoration of normal rhythm. From a practical standpoint these cases may all be regarded as successful, though the measure of success which they achieve varies considerably. The most successful subgroup consists of those in whom normal rhythm was restored more than two years ago and who are still normal at the present time. Some of these have had relapses during the period of observation, but the normal mechanism has been easily restored by further courses of quinidine. Less successful are those who remained normal for two years or more (with or without relapses), but subsequently reverted to established fibrillation. We were at first inclined to regard these cases as unsuccessful, but the fact that they did derive definite and prolonged, though only temporary, benefit, seemed to justify their being considered as at any rate partially successful. The "unsuccessful" group includes (a) those patients in whom quinidine failed to produce normal rhythm, (b) those who

relapsed soon after the restoration of normal rhythm, and (c) those in whom normal rhythm was restored and maintained, but who died within a few months of discharge from hospital, or derived no obvious benefit therefrom. It must be recognised that there is no hard-and-fast line between these different groups. Probably some of the cases which failed to respond would have turned over if more quinidine had been given; but, in view of our experience that cases in which large doses of quinidine are required to produce normal rhythm tend to relapse, we did not feel justified in pushing the treatment farther. Similarly, some of the early relapses might have been prevented if the change to normal rhythm had been followed up by a larger "holding dose" of quinidine. On the other hand, there are the cases at present normal. There can, we are afraid, be little doubt that some of these will sooner or later revert permanently to fibrillation, and fail to respond to further courses of quinidine. Though fully conscious of its inherent defects, nevertheless we are inclined to think that a classification such as this does serve a useful purpose by helping to give some indication of the scope of quinidine therapy. Of our 22 rheumatic cases 7 failed to respond, 3 died within a few months of the restoration of normal rhythm, 1 died after maintaining normal rhythm for 19 months, 4 relapsed early, and the remaining 7 were "successful." Of the 5 cases in the fibrotic group 2 were "successful," 1 failed to respond, 1 relapsed early, and 1 died shortly after the restoration of normal rhythm.

A. Successful.

	Rheumatic.	Fibrotic.
1. Still normal	5	2
2. Normal for over two years ..	2	0
Total	7 (32%)	2 (40%)

B. Unsuccessful.

	Rheumatic.	Fibrotic.
1. Failed to respond	7	1
2. Relapsed	4	1
3. Died	4	1
Total	15	3

It is interesting to compare these figures with those given by Hay⁸ in his report of cases collected from members of the Cardiac Club in 1923. He divides his cases into two $\frac{1}{2}$ groups, according to whether fibrillation was, or was not, associated with valvular disease of the heart, and each group into three classes—(1) failures, (2) temporary successes, and (3) permanent successes. Hay's class 1 corresponds to our B1, his class 2 to our B2, and his class 3 $\frac{1}{2}$ to our classes A1 and 2. His figures are as follows:—

	Group 1 (with "V.D.H.")	Group 2 (no "V.D.H.")
Class 1 (failure)	78	28
" 2 (temporary success) ..	42	21
" 3 (permanent " ") ..	46 (27%)	35 (40%)
	166	84

Our figures are much too small to have any statistical value, but so far as they go, since most of the cases in Hay's group 1 were probably rheumatic, there is a fairly close agreement.

Group A. Successful Cases.

CASE 1.—A tramcar trolley boy, aged 18, was admitted to hospital in April, 1923, with rheumatic carditis, early mitral stenosis, and auricular fibrillation. 1.2 g. of quinidine restored normal rhythm, which has persisted ever since without further treatment. Since September, 1923, he has been working at a tram depot 48 hours per week. In June, 1926, the heart was slightly enlarged with a systolic, and a short diastolic, murmur at the apex. His only spell off work during the whole of this period was three weeks in December, 1927, when he complained of "rheumatic" pains in the arms and abdomen.

CASE 2.—A commercial traveller, aged 38, was first seen in July, 1924, complaining of palpitation and pain in the

⁸ With the third (the thyrotoxic) group we are not concerned in this paper.

¹ The patients we classified as B3 might have been in either class 2 or 3 of Hay's series.

chest of several weeks' duration. For some years he had had attacks of "palpitation" lasting for half an hour up to several hours. He had always been very active and played golf and lacrosse. There was a history of rheumatism as a child and scarlet fever in 1903. The heart was not enlarged, but its action was irregular and there was an apical systolic murmur. The electrocardiogram showed auricular fibrillation. In May, 1925, he was admitted and treated with quinidine. Six doses of 0.4 g. restored normal rhythm. This has been maintained without relapse up to the present date. Ventricular extrasystoles cause palpitation at times, chiefly at night. He is able to walk several miles daily, and to go upstairs without distress or shortness of breath.

CASE 3.—A motor driver, aged 41, was admitted to hospital in September, 1925, complaining of dyspnoea and pain in the stomach which troubled him chiefly at the end of his day's work. Dyspnoea had been present for a year and the "dyspepsia" for about five months. He had had bronchitis each winter for several years and two attacks of "influenza," the last in 1922. As a child he had chorea. Auricular fibrillation was present on admission and had

FIG. 1.

probably existed for a year. The resting heart-rate was about 80 per minute. There was an accentuated first sound and a systolic murmur at the apex. The maximal impulse was in the fifth space in the mid-clavicular line, but the area of cardiac dullness was not increased to the right. Quinidine treatment was commenced on Oct. 7th and the heart became regular on the 9th, after six doses of 0.4 g.; 0.2 g. of quinidine was taken daily until October, 1927, when the patient had to be operated on for acute appendicitis. Since then he has had no quinidine, but nevertheless the cardiac mechanism has remained normal.

CASE 4.—A pressman in a rubber factory, aged 31, was admitted to hospital in February, 1926, with dyspnoea and palpitation, which had troubled him since 1923 and had been worse for six months before admission, though he had been able to carry on his work until January. There was a history of sore-throats, but there had been no other rheumatic manifestations. He was refused for the Army in 1915 on account of V.D.H. On admission to hospital he was found to have mitral stenosis and auricular fibrillation. Quinidine was given from March 5th to 11th without success (total 4.6 g.). A second course on March 30th-31st, consisting of four doses of 0.4 g., restored normal rhythm, which has been maintained up to the present date. A daily holding dose of 0.2 g. has been given since normal rhythm was first restored. This patient was able to resume his work in April, 1926, and has worked continuously ever since. He now has dyspnoea only after unusual exertion.

CASE 5.—A pattern maker, aged 59, was admitted to hospital in April, 1926, with orthopnoea and oedema of the legs. He had only left off work a few days previously. The heart was considerably enlarged to the left. Auricular fibrillation was present with an apical systolic murmur and a poor first sound, the second sound being accentuated at the base. The blood pressure was raised. There was no rheumatic history. A drachm of the tincture of digitalis was given every six hours for four days and smaller doses during the next two days, and normal rhythm was restored. He has not done any active work since discharge from hospital in May, 1926, but is able to enjoy a quiet life, and there has been no tendency to revert to fibrillation.

CASE 6.—A carter, aged 62, who had previously had good health, was treated with quinidine sulphate in March, 1923, for auricular fibrillation, which had probably been present for six months, during which period he had been short of breath and had complained of some epigastric discomfort. There were no signs of congestion. The first sound was somewhat impure at the apex, and both sounds were faint at the base. 4.0 g. of quinidine, given during a period of four days, produced pure flutter (Fig. 2), and the drug was discontinued for ten days. Fibrillation returned (Fig. 3). 1.6 g. in a day then sufficed to produce normal rhythm, which was accompanied by a definite improvement in the subjective symptoms. In this case a diffuse rash of small red macules appeared on the chest, abdomen, and upper part of the back, after quinidine. It itched at first, but gradually faded and then ceased to cause trouble. Normal rhythm (Fig. 4) persisted for 20 months, and then auricular fibrillation recurred for no apparent reason, in spite of the fact that he was taking a small daily holding dose of quinidine. The drug was therefore increased (Fig. 5), and normal rhythm was restored in January, 1925, since when auricular fibrillation has recurred four times. In April, 1925, it was present for 24 hours. In June, 1925 (Fig. 6), it was present for five days following a cold, and in December, 1925, the patient reported that the heart had been irregular for a period of five hours, but had spontaneously returned to normal. On each of the other occasions normal rhythm was easily restored by quinidine. In May, 1926, the patient was able to get about without any symptoms of distress. Normal rhythm continued until June, 1927, when the pulse became irregular owing to sino-auricular block (Fig. 7), and a week later fibrillation (Fig. 8) again developed, the quinidine having been omitted for some days. Seven weeks later, when quinidine was resumed, normal rhythm (Fig. 9) was restored and has since been maintained in spite of an attack of bronchitis in the early part of this year.

This case is of particular interest, for the relapses have afforded repeated opportunities for comparing the general condition during fibrillation and sinus

quickly cleared up and did not upset the heart mechanism. The quinidine was reduced until 0.2 g. was being taken daily, and gr. 1/600 of Nativelle's digitalin every other day. This was continued until June, 1927. He was able to carry on his work till December, 1927, when attacks of palpitation and dyspnoea became troublesome on more than mild exertion. In February, 1928, he had to go to bed for two weeks on account of the dyspnoea, and has been in bed a

few days since then. When last seen in June of this year the heart rhythm was normal and he was continuing to take 0.2 g. of quinidine daily.

CASE 8.—A working-class woman, aged 26, whose cardiac lesion dated from an attack of rheumatic fever in childhood, developed auricular fibrillation during a subsequent rheumatic attack, following confinement. When first seen she had advanced mitral stenosis with enlargement of the liver. Normal rhythm was restored by 1.0 g. of quinidine in June, 1923, and maintained for over two years, despite the birth of a full-time child (fourth pregnancy). A fifth pregnancy, however, had to be terminated at three months, in September, 1925, owing to heart failure associated with the recurrence of fibrillation. Two short courses of quinidine at that time failed to restore normal rhythm. She was readmitted in July, 1926, and quinidine was again administered. The first course of 0.8 g. caused vomiting, but four days later 2.0 g. restored normal rhythm which was maintained for five months. In January, 1927, a further course of quinidine (4.8 g.) once more restored normal rhythm, and a daily holding dose of 0.4 g. was given. From January to the end of February, 1927, auricular fibrillation and flutter occurred in paroxysms, finally giving way to continued fibrillation which has persisted. Since reversion to fibrillation, 15 months ago, it has been possible efficiently to control the ventricular rate with digitalis. This patient is able to carry on her full household duties, though her exercise tolerance is not quite so good as it was during the first long spell of normal rhythm. Her heart is now greatly enlarged, and radiographic examination shows that the shadow of the left auricle forms part of the right border of the heart (Fig. 9). This case illustrates a sequence of events which one might reasonably anticipate when the cardiac lesion is progressive. After each relapse a larger dose of quinidine was required to restore normal rhythm, and the subsequent relapses tended to follow more quickly. In this case we had hopes of obtaining a permanently successful result, but were doomed to disappointment. The fact that normal rhythm was maintained throughout pregnancy and labour seemed most promising, but apparently the cardiac lesion was progressive and eventually got the upper hand.

CASE 9.—A general labourer, aged 35, was admitted to hospital in August, 1923, with slight cardiac enlargement, auricular fibrillation, mitral stenosis, and aortic incompetence. He had been invalided out of the army with rheumatism seven years previously. His liver was enlarged and tender. Normal rhythm was restored after two courses of quinidine of 4.0 g. and 7.2 g. respectively, and maintained for a year with one relapse lasting 12 days. The second attack of fibrillation again produced epigastric tenderness. Normal rhythm was restored and maintained for two months with a relapse of two days. A third time normal rhythm was restored and held for six months, and a fourth rhythm was restored and held for six months, and a fourth rhythm was restored and held for six months. After another relapse lasting ten days normal rhythm was again restored and held for three months. In all, normal rhythm was maintained for three years, though there were six relapses of short duration, each accompanied by signs of cardiac failure and epigastric tenderness. After the sixth return to auricular fibrillation in September, 1926, quinidine failed to restore the normal

FIG. 3.

March 26th, 1923. Chest lead showing fibrillation.

rhythm. The patient, who is an intelligent and observant man, is most emphatic about the relief which on each occasion has accompanied the restoration of the normal mechanism. There is a second reason why this case is worthy of notice. It is one in which we did not expect to obtain a successful result. An elderly man, the ventricular complex of whose electrocardiogram (Figs. 2-8) is strikingly abnormal, could hardly have been regarded as a favourable subject. In fact the only redeeming feature—and one to which hitherto we have probably not attached sufficient importance—was the absence of congestive heart failure. The success in this case tempts one to give quinidine a trial in some of the other "fibrotic" cases which hitherto we have passed over as unsuitable.

CASE 7.—A mission secretary, aged 40, was admitted in February, 1926, with rheumatic carditis, congestive heart failure, and auricular fibrillation. His cardiac symptoms dated from an attack of chorea at the age of 11. Digitalis was given for four weeks, by which time all signs of failure had disappeared. A course of quinidine treatment was commenced on March 24th, and two days later, after 2.4 g. of the drug had been taken, the heart's action became regular, except for occasional extrasystoles. A week later the patient had acute pain in the region of the spleen, suggestive of infarction, and was slightly jaundiced. This

rhythm, in spite of five courses of treatment totalling 30 g. of the drug. In March, 1927, he was ill for three weeks at home and was then readmitted to hospital with embolic hemiplegia. In April he was discharged much improved, but still fibrillating, and was able to do light work until January, 1928, when he died after 36 hours' illness. The repeated relapses in this case appeared to be associated with emotional disturbances to which the patient was unduly susceptible.

Beneficial Effects.

In the majority of cases the restoration of normal rhythm seems to benefit the patient in two ways. He feels more comfortable—he is no longer conscious that he has a heart—and his tolerance for exercise is increased. Blumgart's¹ observations show that whereas digitalis is capable of controlling the resting ventricular rate in patients suffering from fibrillation, it fails to protect the ventricles from the exaggerated response to exercise, for, although the maximum rate attained on exertion is lower, the actual increase in rate is even greater than in the patient who has not taken digitalis. If this were the whole story, it would be easy to understand why the restoration of normal rhythm should increase the tolerance for exercise; but Blumgart goes on to point out that the heart in which normal rhythm has been restored by quinidine exhibits the same type of response to exercise as it did previously. If this be so, one is bound to conclude that the abnormal response to exercise is due, not to the abnormal rhythm but, to some other factor, probably the associated myocardial insufficiency. We cannot

FIG. 4.

May 27th, 1924. Leads I, II, and III, showing sinus rhythm. The spreading, slurring, and large amplitude of the Q.R.S. complex is suggestive of impaired conductivity in the right branch of the auriculo-ventricular bundle. These features have remained practically unaltered during the five years that the patient has been under observation. The smaller amplitude of the deflexions in some of the later records is accounted for by the fact that these were taken at the standard sensitivity but with a lower magnification—i.e., with the camera closer to the galvanometer, so that an E.M.F. of 3 millivolts gives a deflexion of less than 30 mm.

express any opinion on this point, for we have not recorded the heart rate after exercise in our patients. But we have no hesitation in saying that, in the "successful" cases in our series, the patients have been able to lead a more active life than they could before the restoration of normal rhythm. Clark-Kennedy³ came to the same conclusion. He stated that, in his series, sino-auricular (S.A.) rhythm raised the cardiac efficiency to a higher level than when auricular fibrillation was present, and the ventricular rate controlled by digitalis.

Group B.1. Complete Failures.

Tachycardia.—Of the eight cases in which quinidine failed to restore normal rhythm the treatment had to be abandoned on account of toxic symptoms in three

instances. A woman of 31 (Case 10) with a rheumatic mitral stenosis and congestive heart failure, developed distressing palpitation on two occasions after a single dose of 0.2 g. The same was true of another woman (Case 11) who at the time showed no signs of heart

FIG. 5.

Dec. 5th, 1924, lead II. Both records show pure flutter with a 2:1 block. The irregularity in the lower record is due to the presence of frequent premature beats (P.B.), each of which is followed by a compensatory pause. This type of arrhythmia in which the flutter was complicated by premature beats of supra-ventricular origin was observed on three occasions in this patient during the transition from fibrillation to sinus rhythm.

failure. Both these patients subsequently died from cerebral embolism, the former three months and the latter three years after discharge from hospital.

Palpitation is a toxic symptom which has been noted by most workers, and may be sufficiently severe to render further treatment inadvisable. Levy¹⁰ records two cases of heart failure which he considers were directly attributable to ventricular tachycardia. Parkinson and Nicholl¹¹ reported four cases in which signs of acute heart failure followed quinidine, but they suggest that this may have been due, not merely to the tachycardia but to a prejudicial effect of the drug on the myocardium. Frey⁶ and others have reported instances of sudden, though only temporary, collapse with loss of consciousness and failure of respiration, and Clark-Kennedy³ observed cerebral symptoms with partial or complete loss of consciousness in three of his cases.

In a man of 37 (Case 12), with no rheumatic history, treated in 1923, 13 g. of quinidine failed to restore normal rhythm and the drug had to be discontinued on account of headache and abdominal pain. This patient's condition does not appear to have become any worse, and for the past four years he has been able to carry on his work as a fimsmith.

Embolism.—In one of our early cases (Case 13), a woman of 46 with orthopnoea and oedema, cerebral embolism occurred shortly after the commencement of a course of quinidine treatment. The fact, however, that fibrillation was still present suggests that the quinidine may not have been any more to blame for this accident than for the similar catastrophe in the two cases in which the drug had been discontinued on account of palpitation. The only other case in our series in which embolism occurred while the drug was being given was Case 7, in which the resumption of normal rhythm probably was instrumental in producing splenic infarction, which, however, led to no serious results. Embolic phenomena are so common in old-standing cases of fibrillation, as is shown even in the present small series, that we are inclined to think that quinidine does not deserve all the blame it has received in this respect.

If the resumption of auricular contraction were responsible for dislodging a thrombus, one would

expect embolism to occur most frequently at the time, or at any rate very soon after the restoration of sinus rhythm; but experience does not bear this out. Viko, Marvin, and White¹² found that in 452 cases treated with quinidine the incidence of embolism was no higher than in 200 control cases in which it had not been given.

In a woman of 32 (Case 14) with cardiac enlargement and mitral stenosis but no œdema, three courses of quinidine failed to restore normal rhythm. Her condition has become slowly worse during the past four years. In a man of 36 (Case 15) with mitral stenosis and dyspnoea on exertion, fibrillation was converted to 2:1 flutter by two courses of quinidine; but he failed to develop normal rhythm, and subsequently relapsed to fibrillation. His condition four years later remains practically unchanged. In a labourer (Case 16) of 32 with aortic incompetence, mitral stenosis, and considerable cardiac enlargement, who had rheumatic fever in 1916, large doses of quinidine failed to restore normal rhythm. During the past three years he has been treated with digitalis and his cardiac condition has shown little change.

CASE 17.—A salesman, aged 33, who three months previously had been able to play tennis, was admitted to hospital in 1925 with mitral stenosis, aortic incompetence, and auricular fibrillation, but no signs of heart failure. There was a definite rheumatic history. Two courses of quinidine failed to restore normal rhythm, but digitalis sufficed to control the heart-rate and he was able to follow his occupation, which was not strenuous, until May, 1928, when he died after a short illness.

Ventricular Fibrillation.—Hay⁸ in his series of 286 cases, which includes not only fibrillation but also flutter and paroxysmal tachycardia, records eight cases of sudden death which did not appear to be due to embolism. One of us has seen elsewhere a case in which it seemed probable that quinidine had caused sudden death by producing ventricular fibrillation. This, fortunately, is an extremely uncommon occurrence. Here again it is not possible to be certain that the drug has been responsible for the catastrophe, since ventricular fibrillation does occur spontaneously in patients who have never been treated with quinidine. An instance in point has recently been reported by one of us.² The patient was a man of 25, with old-standing rheumatic carditis, auricular fibrillation, and extreme dilatation of the left auricle. He was being

fatal issue in cases of auricular fibrillation in which no sufficient cause of death can be found post mortem.

Group B2. Relapses.

In the following cases the restoration of normal rhythm proved to be no more than a merely transient affair.

CASE 18.—A clog sole cutter, aged 42, who had had rheumatic fever in 1903, began to suffer from shortness of breath

FIG. 7.

June 26th, 1927. Leads I, II, and III. Auricular fibrillation with a ventricular rate of about 140 per minute.

on exertion in April, 1921. He was admitted to hospital in February, 1922, with auricular fibrillation, but no evidence of cardiac enlargement nor of any valvular lesion. 2.4 g. of quinidine produced pure flutter. Auricular fibrillation recurred when the drug was discontinued. A second course of quinidine again produced flutter, but normal rhythm supervened after 4.6 g., and persisted for a fortnight. This patient refused further treatment since the quinidine provoked headache and abdominal discomfort.

CASE 19.—A hatter, aged 58, was admitted to hospital in October, 1925. There was a history of rheumatism at the age of 38. The heart was not enlarged and there were no

FIG. 6.

June 17th, 1927. Leads I and II, showing sino-auricular block. The irregularity in lead II is associated with variability in the form of the T-wave.

treated by rest in bed with small doses of digitalis, and appeared to be making very satisfactory progress. Five days after admission to hospital, when using the bed-pan, suddenly and without warning he collapsed, and died within five minutes. Autopsy failed to reveal the cause of death. The general condition of this patient during the period he was in hospital was apparently so satisfactory that, if his sudden and unexpected collapse had followed the administration of quinidine, one would have been tempted to attribute it to the use of that drug. Since he never had quinidine, this contingency does not arise, but it leads one to question the validity of the evidence on which quinidine is sometimes blamed for bringing about a

signs of cardiac failure, but he had auricular fibrillation and mitral stenosis. Six doses of quinidine sulphate totalling 2.4 g. restored normal rhythm. No holding dose was given. In this case it is not possible to say how long sinus rhythm was maintained as the patient was not seen till readmission to hospital a year later, when auricular fibrillation was present together with signs of cardiac failure. He improved with digitalis treatment, but on this occasion quinidine was not given. Since then he has been unable to work, partly on account of his cardiac disability, but chiefly because he is not mentally capable.

CASE 20.—A cotton overlooker, aged 37, was admitted to hospital with auricular fibrillation in February, 1926. There was a history of rheumatic fever at the age of 11. There was no obvious valvular lesion and no cardiac enlargement. 3.0 g. of quinidine restored normal rhythm,

which only held for a week. A second course of quinidine was given and 2.0 g. again restored normal rhythm; this was maintained with a daily dose of 0.2 g. till his discharge on March 20th, when the fibrillation returned and has persisted to the present date. Since leaving hospital he has been able to follow his occupation, but during the past year he has found the work rather strenuous and has required to have periodic rests to relieve the palpitation, dyspnoea, and precordial pain which develop when he is tired.

† CASE 21.—A clerk, aged 55, was admitted to hospital in October, 1924, complaining of palpitation and loss of mental

FIG. 8.

June 1st, 1928. Leads I, II, and III. Sinus rhythm.

concentration. Dizziness had been present for four months. As a child he had been subject to frequent "sore throats." On admission he was found to have mitral stenosis, auricular fibrillation, with slight enlargement and tenderness of the liver. Quinidine (0.4 g.) was administered twice daily from Oct. 7th to 9th, and sinus rhythm was restored after the third dose. The dose was reduced to 0.2 g. daily until the 23rd and was then reduced to 0.1 g. daily. The patient's transference to another ward on Oct. 27th coincided with reversion to fibrillation, but further treatment with 0.4 g. quinidine twice daily again restored normal rhythm after six doses. His condition improved considerably and he was allowed to go home on Nov. 5th. Fibrillation returned soon after discharge, but he was able to work for a short time. On Dec. 27th he developed an embolic hemiplegia and died a week later.

CASE 22.—A married woman, aged 48, was admitted in March, 1926, with pain in the lumbar region and dyspnoea of three years' duration. The heart was slightly enlarged to the left, but the sounds were good, and there was a soft apical systolic murmur. Apart from auricular fibrillation no other abnormal signs were present. Quinidine was given for four days without success. Five days later normal rhythm was restored after 2.8 g. of quinidine. A holding dose of 0.4 g. twice daily was given until discharge at the end of the month, and was ordered to be continued. The patient did not attend for further treatment, and fibrillation recurred soon after leaving hospital. Restoration of normal rhythm did not appear to benefit this woman, and she has continued in good health without further treatment. She was last seen in March, 1928, when the fibrillation was still present. The pulse-rate was 80, the first sound was blurred at the apex, but elsewhere both sounds were clear. There was no cardiac enlargement nor oedema. She was not having any treatment.

Group B3. Little or no Benefit from the Restoration of Normal Rhythm.

Four patients in whom the restoration of normal rhythm was unaccompanied by any obvious improvement in their general condition, all died within seven months of discharge from hospital. The one remaining patient in this group (Case 24) lived for 19 months.

CASE 23.—A machinist, aged 50, with old-standing rheumatic carditis and mitral stenosis became normal in June, 1926, after six doses of 0.4 g. of quinidine. A daily holding dose of 0.4 g. was given. On discharge from hospital she was able to resume her work, but in November, 1926, she had an attack of acute pleurisy. After this she rapidly lost ground and died in January, 1927.

CASE 24.—A married woman, aged 31, who had been short of breath for 15 years, and getting worse during the last 12 months, was admitted to hospital with mitral stenosis and auricular fibrillation. The heart was slightly enlarged, and the liver was just palpable. In April, 1925, 3.0 g. of quinidine were given without success. A second course of 4.0 g. four days later restored normal rhythm. Two weeks later she was allowed to get up, and felt much better. She was able to walk about without distress. In July there was a brief relapse to auricular fibrillation, in spite of a daily dose of quinidine. Normal rhythm returned, however, without increasing the dose and was maintained until the end of 1926, when she took a turn for the worse and died early in January, 1927.

This is a border-line case which might have been regarded as successful for a short period of time.

CASE 25.—In a woman, aged 29, who had suffered from dyspnoea for five years, 2.8 g. of quinidine restored the normal rhythm, but the patient refused further treatment owing to headache and nausea. Her heart was greatly enlarged, but there was no venous congestion nor oedema. Shortly afterwards the patient returned home and died within a few weeks.

CASE 26.—A fruiterer, aged 26, with mitral stenosis and moderate cardiac enlargement, turned from auricular fibrillation into auricular flutter with 1.2 g. of quinidine. A further 1.6 g. restored the normal mechanism which persisted till death a month later.

CASE 27.—A mechanic, aged 42, was admitted in January, 1925, with chronic interstitial nephritis and auricular fibrillation. There was a six months' cardiac history. After three weeks' rest in bed and treatment with digitalis, quinidine was given. Three doses of 0.4 g. restored normal rhythm, and this was maintained. By the end of February all signs of cardiac failure had disappeared and he was able to walk about. He went home, still taking quinidine daily, but died seven weeks later from uremia. The pulse remained regular to the end.

Paroxysmal Auricular Fibrillation.

We have made no reference in this paper to the use of quinidine in paroxysmal fibrillation. In conditions such as this, where the attacks occur at irregular

FIG. 9.

Radiogram of chest in Case 8. L.A.=Shadow of left auricle. R.A.=Shadow of right auricle.

intervals, vary in duration, and terminate spontaneously, it is exceedingly difficult to assess with any certainty the value of the therapeutic agents which have been employed. Parkinson and Nichol¹¹ reported beneficial effects in three out of five cases under their care. As they say, one would naturally expect that a drug which can abolish established fibrillation would be likely to ward off, or at any rate to reduce the frequency of, attacks in the paroxysmal form of the disorder. We are inclined to think that

the reason why quinidine is not more uniformly successful in this type of case is that there are two distinct varieties of paroxysmal auricular fibrillation, the one a mere precursor of the established condition, the other a derangement of the cardiac mechanism, which shows little or no tendency to become permanent, and is more closely allied to true paroxysmal tachycardia. In one such case which we have now had under observation for six years, during which period attacks have occurred about once a fortnight, quinidine was given daily in varying doses for 12 months. It failed to produce any obvious effect, either on the duration or on the frequency of the attacks; but, since this case raises several issues which do not come within the scope of the present paper, we do not propose to refer to it in detail here.

Method of Administering Quinidine.

We have from time to time modified our technique in the administration of quinidine both as regards the total quantity given per diem and the interval between successive doses. The method which we now generally adopt is, first having got the patient fully digitalised, to give a preliminary dose of 0.2 g. of quinidine to exclude the possibility of an idiosyncrasy to the drug. Twenty-four hours later 0.4 g. is given in the form of a cachet, and this is repeated every two hours for five doses, or until normal rhythm returns. If necessary another five doses are given on each of the two succeeding days. Generally, however, sinus rhythm is restored on the first day.

The after-treatment of patients who respond to quinidine is a subject about which opinion is divided. Emanuel⁴ stated that he had found no advantage in persevering with small doses of quinidine after sinus rhythm had once been established. Hay⁷ expressed a similar opinion in his first paper, but in his report⁸ of the collective experience of members of the Cardiac Club he states that the general opinion seems to be in favour of giving the drug for some time after the restoration of normal rhythm. Fraser⁵ considers that it is probably advisable in all cases to continue giving quinidine for some weeks after normal rhythm has resulted, though in gradually decreasing doses. Clark-Kennedy³ is of opinion that discontinuation of the drug generally leads to relapse. We are inclined to think that no one line of treatment is suitable for all cases. The tendency to relapse is much more pronounced in some cases than in others. The two extremes are represented on the one hand by patients like our Case 1, in which no holding dose was given and sinus rhythm has persisted for five years, and on the other by cases such as those in Group B2, which persistently relapse in spite of a holding dose. To carry the contrast a step further, there are people with healthy auricles which never have fibrillated, and are never likely to fibrillate, while there are others who have fibrillated for some time and will in all probability go on fibrillating for the rest of their lives, and in whom sinus rhythm cannot be restored. The former have no need for quinidine, while in the latter it achieves no result. There are, however, a large number of cases which lie between these two extremes. It is in them that after-treatment with quinidine is likely to hold the balance between fibrillation and normal rhythm and to prevent relapse. On this hypothesis we have based the routine treatment which we now employ. When normal rhythm is first restored we give no holding dose, for if it should prove unnecessary so much the better. When, however, the first relapse occurs we give a holding dose of 0.4 g. per diem for a month or six weeks, and half that dose for the next two or three months. In the event of a subsequent relapse the quinidine is continued indefinitely in such quantity as appears necessary to maintain sinus rhythm.

Summary.

In an unselected series of 27 hospital cases of auricular fibrillation, all of which were first treated with quinidine more than two years ago, definite and lasting benefit was obtained in nine instances. In 8 cases the drug failed to produce normal rhythm, and in

the remaining 10 cases though fibrillation was arrested, either the restoration of the normal mechanism proved to be a merely transient event, or the patient derived no definite benefit therefrom. In 5 cases the aetiological factor appeared to be a chronic myocardial fibrosis, and in the remaining 22 the cardiac lesion was definitely or probably rheumatic.

Some of the dangers of quinidine therapy are considered and the method of administration is discussed.

We are indebted to the other members of the staff of the Manchester Royal Infirmary for permission to study and to follow up the after-histories of cases under their care in the hospital; and we should also like to acknowledge the help which we received in the earlier part of this investigation from Dr. Sylvia K. Hickson.

ACTION OF RADIATION ON BLOOD-SUPPLY OF TUMOURS.

By J. C. MOTTRAM, M.B. LOND.,

DIRECTOR OF THE RESEARCH DEPARTMENT OF THE RADIUM INSTITUTE, LONDON.

So much attention has been paid to the direct action of radiation on tumour cells that its other effects on tumours have been neglected. Previous papers have brought forward experimental evidence to show that the action of radiation on blood-vessels and on blood-supply is very important, and that it will explain many experimental and clinical findings, besides giving a useful working hypothesis for therapy. In the present paper I insist once more on the importance of the effect on the blood-supply when irradiating living tissues or tumours. The difference between the exposure of tumours *in vitro* and *in vivo* has been dealt with.¹ When tumour cells are left in the body after exposure *in vivo* they suffer from the damaging effect of a lessened blood-supply as well as from the direct action of the radiation, and so are more easily destroyed than when removed at once and implanted into another animal, where they do not suffer from any disturbance of blood-supply. The dose of radiation can be adjusted so that the cells die when implanted four or five days after exposure, whereas they live when implanted at once. This difference was shown to be associated with an interference with the blood-supply occurring four to five days after exposure. Thus two actions of radiation were differentiated: (a) direct destructive action on the tumour cells, and (b) indirect damage from an interference with the blood-supply.

The experiments here described deal with the difference between the susceptibility of fast- and slow-growing tumours. Clinically, fast-growing tumours appear to be more susceptible than slow. Experiments were made *in vitro* to see whether this was true under experimental conditions. Four tumours were chosen: the fast-growing Jensen's rat sarcoma (J.R.S.), the slow-growing rat sarcoma No. 35, the fast-growing mouse carcinoma T/63, and the slow-growing mouse carcinoma "Twort." Pieces of tumour approximately 1 c.mm. in size were placed between sheets of mica 0.04 mm. thick and exposed to a radium applicator. The applicator used throughout these experiments was 110 mg. $\text{RaBr}_2 \cdot 4\text{H}_2\text{O}$,

area 2×2 cm., screen 0.12 mm. silver. The pieces were then inoculated into the flanks of animals, control unirradiated pieces being placed in the opposite flanks. The results are given in Table I.

The figures show that there is no decided difference in susceptibility between tumour cells from fast- and

In contrast to the previous results a large difference in susceptibility is here seen; the fast-growing tumours are far more easily destroyed. Here the conditions of radiation are much more favourable for the survival of the tumour cells than in the experiments summarised in Table I. In the experi-

ments *in vitro* the tumour material was only 1 mm. thick and was separated from the radium by only a thin sheet of mica, whereas in the experiments *in vivo* the tumours were approximately 5 mm. thick and separated from the radium by the skin and subcutaneous tissues. Other things being equal, the dose required to destroy the tumour cells should be much greater for the exposures *in vivo*. This holds good for the slow-growing tumours, the lethal dose being raised from 30 to 80 minutes for the sarcoma and from 25 to 50 minutes for the carcinoma. In the fast-growing tumours the difference is not seen; from this it may be argued that here some extra destructive action is added which is not present when slow-growing tumours are exposed *in vivo*. In the analysis of these results the comparison of the sarcomas with the carcinomas has been avoided. The differences seen are not sufficiently large to warrant any useful conclusions.

FIG. 1.

FIG. 2.

Diameter of field = 0.93 mm. Stippled areas = tumour; black areas = blood-vessels; Fig. 1 = T.63; Fig. 2 = Twort; Fig. 3 = slow-growing sarcoma; Fig. 4 = J.R.S.

slow-growing tumours; the slow-growing tumours are a little more susceptible than the fast, the lethal doses being 30 as against 40 minutes for the sarcomas, and 25 as against 30 for the carcinomas. If, therefore, fast-growing tumours are clinically more susceptible the difference is not due to any difference in the susceptibility of the tumour cells. Similar results occur if the tumour cells are exposed in the living animal, removed immediately after exposure and tested in the same way.

Fast-growing Tumours more Susceptible *in Vivo*.

Experiments *in vivo* were next carried out. Animals were inoculated in both flanks with pieces of tumour approximately a cubic millimetre in size. The resulting tumours were repeatedly measured, and when one of them had grown to 5×5 or 6×4 mm. of superficial area it was irradiated. The other tumour served as a control; its growth was watched and if it did not grow progressively the animal was discarded. Thus, by using only animals in which the control tumours grew progressively, all effects of immunity were avoided. The radiated tumours were measured thrice a week to see whether they disappeared or not. The results are given in Table II.

FIG. 3.

FIG. 4.

The Heightened Susceptibility due to Interference with Blood-supply.

The suggestion is that this extra destructive action, which operates more in the case of fast- than slow-growing tumours, is an interference with blood-supply, on which radiation is known to have a deleterious

The denominator of each fraction indicates the number of animals used and the numerator the number which grew tumours. Only those animals which grew progressive tumours on the control side were included. Thus the effects of immunity were ruled out. With "J.R.S." and "Twort" concomitant immunity is common, so that very large numbers of animals had to be employed to obtain the data.

action. If we knew that the fast-growing tumours were living at the top of their blood-supply this explanation would suffice, and the fact that fast-growing tumours especially tend to undergo necrosis suggests that it is so. Further, the blood-supply of tumours, and especially of fast-growing undifferentiated tumours, is largely sinusoidal and therefore inefficient and likely to be interfered with easily.

Direct evidence is, however, available. The state of the blood-supply of tumours of mice can be seen through the thin skin during life after depilation of the hair. Progressively growing tumours are coloured rosy pink; pressure blanches this colour, which returns quickly when the pressure is released. After radiation a change becomes visible about the third day in tumours which are going to disappear; the colour changes to a deep purple, which is blanched with difficulty, and the return of which is delayed. Evidently the circulation is obstructed. Subsequently the tumour becomes gradually pale and bloodless, changing from purple through orange and yellow to a dirty white colour. During this period the tumour is decreasing in size. Microscopic examination of tumours confirms these observations.¹

Now as these blood changes always accompany the disappearance of the tumours, it follows that the changes occur after smaller doses of radiation in the fast-growing tumours than in the slow. The question arises: Why do fast-growing tumours suffer a greater obstruction of their blood-supply than do slow-growing ones? Previous work^{2,3} has shown that at least two factors are concerned—changes in the blood-vessels themselves and changes in the surrounding cells. Changes in the blood-vessels such as swelling of the endothelial cells must operate alike for both fast- and slow-growing tumours—and it is more likely that some difference outside the blood-vessels is the determining factor. By taking special precautions to preserve the blood content of tumours during removal and preparation the relationship between blood-supply and tumour cells can be well demonstrated. From such material the following drawings were made on squared paper, using a squared graticule in the eyepiece. These diagrams were chosen from a large number of specimens as representative of the average condition. They are here used only to help the description in the text and not as proof of the differences, which can only be obtained by examination of a large number of stained slides.

Comparing T/63 with Twort it is seen that in T/63 all the spaces between the blood-vessels are closely packed with cells, whereas in Twort connective tissue spaces, free of tumour cells, are to be seen. In other words, the masses of tumour cells around the blood-vessels are larger, deeper, and denser in T/63 than they are in Twort. The same holds good when J.R.S. and slow sarcoma are contrasted; the area of cells per blood-vessel is larger in J.R.S.

It is now possible to suggest why the blood-supply of fast-growing tumours, with cells abundantly and closely packed around the blood-vessels, is especially interfered with by radiation. I have shown³ that the nuclei of cells swell to about three times their normal size (superficial area) on about the second or third day after irradiation. This increase in bulk must take place at the expense of and bring pressure to bear upon surrounding tissues and structures. Thus capillaries and veins will be pressed upon, and in fast-growing tumours where the intervascular spaces are closely packed with tumour cells this will take place to a greater extent than where the tumour cells are less closely packed, as in slow-growing tumours. According to these findings, therefore, the rate of growth is not primarily the determining factor; it is because closely packed cells are commonly found in fast-growing tumours that these are especially susceptible to irradiation.

The radium used in these researches was on loan from the Medical Research Council. I am indebted to Dr. J. A. Murray, of the Imperial Cancer Research

Fund, for the supply of the tumours used in these researches.

ADDISON'S ANÆMIA:

THE EFFECT OF TREATMENT ON THE INTESTINAL INFECTION.

By F. A. KNOTT, M.D., M.R.C.P., D.P.H. LOND.,
HEMATOLOGIST TO GUY'S HOSPITAL.

So many excellent aetiological reviews of Addison's anæmia have recently been published, notably those by Hurst,¹ Davidson,² and Davidson, McCrie, and Gulland,³ that very little repetition is necessary. For the purpose of this note it may be emphasised that consistently good results are being reported as a result of liver treatment and that all observers are now agreed upon the constant presence of complete achlorhydria and intense gastro-intestinal sepsis, particularly the development, by both descending and ascending infection, of a bacterial flora of faecal type throughout the whole length of the small intestine. As Davidson remarks, if auto-intoxication does not occur in pernicious anæmia it can never occur at all. Any acceptable aetiological theory of the disease must recognise both these factors, and in recent times much attention has been devoted to their reconciliation. Below are recorded a few bacteriological observations, made before and after treatment, in the hope that they may, of themselves and from comparison with the work of others, prove helpful in clearing up this most difficult problem.

During the past four years I have, whenever opportunity occurred, examined the gastro-duodenal and faecal bacteriology of proved cases of Addison's anæmia. The results obtained from 37 patients were published⁴ in January, 1927, and, after comparing my own results with others available at that time, I suggested that the reason for complete failure on the part of so many workers to isolate a specific bacterium in Addison's anæmia arose from the fact that there is no specific organism, the toxins being products in general of the grossly faecal flora which comes to occupy the small intestine. In the following year Davidson, after working on similar lines with 32 cases, suggested that it is unnecessary to state categorically whether the toxin is produced by one or all of the organisms present in such abnormal numbers and position, or even whether it is the result of bacterial action on the ingestion of food materials. This observer's detailed bacteriological results have just been published, and, after discussing them with him personally, I think I can safely say that our results agree in all essential particulars, except that I have recorded a somewhat higher incidence of hæmolytic strains of streptococci in the gastro-duodenal and faecal specimens. The former discrepancy is probably explained by the fact that several of the cases in my series suffered from relatively acute oral and upper alimentary sepsis. I found hæmolytic streptococci in the faeces in one case only, but I have concluded from further experiments that the coliform strains do not produce a true, separable hæmolysin, but, as Davidson suggests, cause rapid hæmodigestion in blood media. Therefore my figures for the incidence of hæmolytic strains of *B. coli* were probably too high. I entirely agree with the general finding by many observers that the anaerobic bacteria, many of which are hæmolytic in normal people, are markedly increased in the faeces in Addison's anæmia. A review of all the bacteriological facts so far established shows that in most of the cases the only organisms which can produce a free hæmolysin and are present in sufficient numbers to elaborate in the intestine enough hæmolysin to allow its absorption in any quantity,

are the anaerobic strains, particularly those which would be classified as *B. welchii*. But there are several reasons for hesitation in accepting this organism as the specific cause of the anæmia. For example, it has been my experience as well as that of several other workers on the subject that, as I pointed out when recording my first series of cases, the anaerobic increase does not especially concern the hæmolytic strains. When these faecal strains of *B. welchii* are isolated such extreme variations are found in the amount of hæmolysin they produce that it is impossible to conclude that an increase in the number of *B. welchii* spores in a faecal specimen necessarily proves that the amount of free hæmolysin in the intestinal contents is raised in corresponding proportion. Several other reservations are carefully discussed by Davidson* in his most recent paper, and need not be detailed here. There is, I think, much to be said for his contention that bacterial hæmolysins are not necessarily of ætiological importance in the disease, and that it is the gastro-intestinal sepsis generally which produces a toxic effect on the liver and prevents it from providing sufficient of that substance which appears to be essential for the proper maturation of the megaloblasts.

Bacterial Content of the Faeces.

The particular concern of the present note is, however, the effect of treatment. Since my original series was published a few more cases have come under observation and, more important, it has been possible to examine some of the original patients after their return to normal. In the first place, the bacterial content of the faeces was estimated before and after successful treatment by high liver diet. Table I.

shows typical results from five cases of Addison's anæmia when the hæmoglobin percentage stood at 40-60 per cent. and 90-100 per cent. respectively, and these are compared with the bacterial counts from five normals. The technique employed is essentially similar to that adopted by both Moench, Kahn and Torrey, and Davidson. The experiments were carried out so far as to estimate the number of living *B. welchii* spores and coliform bacilli as a group, not typical *B. coli communis* only; further refinements were considered unnecessary for the present purpose.

Fresh faecal material was broken up in sterile normal saline in test-tubes of constant size and, after the coarse material had settled, a series of dilutions was prepared with saline, so that each was ten times weaker, until the final dilution represented 1 in 100,000,000 of the original suspension. All the original suspensions were made to match a standard opacity against the same light before the dilution series was commenced. For the detection of the highest dilution containing *B. welchii* spores, previously heated tubes of Robertson's cooked meat medium were used, 1 c.c.m. of the various dilutions being added, and, after heating to 50° C. for 20 minutes the tubes were closed with one-inch caps of vaseline and paraffin and incubated at 37° C. for several days. From those tubes which showed the characteristic *B. welchii* reaction subcultures were made into litmus milk tubes similarly capped and incubated

in order to obtain the characteristic clot. For the estimation of coliform bacilli plates of bile-salt agar were poured after adding 0.1 c.c.m. of each suspension examined.

The figures in Table I. agree in the main with the quantitative estimations of bacteria in the faeces of untreated cases of Addison's anæmia which were made by the observers already quoted, but they also emphasise one very important ætiological point—namely, that the faecal bacteriology is not altered as the result of liver treatment, and cases showing a return to a normal blood picture still retain their intestinal infection.

The results of the van den Bergh reaction applied to the serum are important in relation to the persistently high bacterial counts. In Cases 2 and 4 the originally positive indirect reaction remained, in spite of the relatively normal blood picture, and in Cases 1, 3, and 5 the reaction had quickly become completely negative after liver treatment was commenced and had remained negative up to the time that the bacterial counts were made. If the positive reaction was taken to represent active hæmolysis, then hæmolysis was still occurring in 2 and 4 but had ceased in the others. If the hæmolysis depends upon the amount of absorbable hæmolysin in the intestines, then one would have expected Cases 1, 3, and 5 to show a decided decrease in the intestinal infection, but this was not seen. The disappearance of the positive van den Bergh reaction does not necessarily appear to correspond with a period of reduced intestinal infection.

One would not, I think, expect liver taken by the mouth to influence directly any intestinal infection present, and that it cannot do so is suggested by the result of an experiment which I have carried out several times with slight modifications. Various liver preparations were incorporated in quantities varying from 0.2 to 2 per cent. in the usual agar and broth media used in routine bacteriological examination of faeces, control cultures being made in the same medium free from liver. No indication could be obtained that liver extract or digested liver had any appreciable influence upon the number of organisms growing in faecal cultures.

It seems safe to assume, therefore, that liver treatment has no direct influence on the intestinal infection which all observers agree exists in Addison's anæmia. On the other hand it is possible to reduce to some extent the concentration of bacteria in the intestines by systematic attack upon all the factors which give rise to and maintain this infection—e.g., buccopharyngeal and dental sepsis and achlorhydria. In support of this it may be of interest to mention the findings in two cases of Addison's anæmia which came under observation early in 1924, before the introduction of treatment by high liver diet, in whom

TABLE II.—Addison's Anæmia treated without Liver.

No.	Before treatment. Hb. 40-60 %.		After treatment. Hb. 80-100 %.

systematic eradication of septic foci, administration of dilute hydrochloric acid by the mouth, and a long course of *B. acidophilus* milk produced gradual recovery to a normal blood picture, which has been maintained. At that time only quantitative examinations of the total number of coliform bacilli in the faeces and the relative number of streptococci to coliform organisms on plates were made. In both cases the bacterial counts were noted to fall quite definitely. It is unfortunate that anaerobic counts were not also made. The evidence of only two cases is, of course,

action. If we knew that the fast-growing tumours were living at the top of their blood-supply this explanation would suffice, and the fact that fast-growing tumours especially tend to undergo necrosis suggests that it is so. Further, the blood-supply of tumours, and especially of fast-growing undifferentiated tumours, is largely sinusoidal and therefore inefficient and likely to be interfered with easily.

Direct evidence is, however, available. The state of the blood-supply of tumours of mice can be seen through the thin skin during life after depilation of the hair. Progressively growing tumours are coloured rosy pink; pressure blanches this colour, which returns quickly when the pressure is released. After radiation a change becomes visible about the third day in tumours which are going to disappear; the colour changes to a deep purple, which is blanched with difficulty, and the return of which is delayed. Evidently the circulation is obstructed. Subsequently the tumour becomes gradually pale and bloodless, changing from purple through orange and yellow to a dirty white colour. During this period the tumour is decreasing in size. Microscopic examination of tumours confirms these observations.¹

Now as these blood changes always accompany the disappearance of the tumours, it follows that the changes occur after smaller doses of radiation in the fast-growing tumours than in the slow. The question arises: Why do fast-growing tumours suffer a greater obstruction of their blood-supply than do slow-growing ones? Previous work^{2,3} has shown that at least two factors are concerned—changes in the blood-vessels themselves and changes in the surrounding cells. Changes in the blood-vessels such as swelling of the endothelial cells must operate alike for both fast- and slow-growing tumours—and it is more likely that some difference outside the blood-vessels is the determining factor. By taking special precautions to preserve the blood content of tumours during removal and preparation the relationship between blood-supply and tumour cells can be well demonstrated. From such material the following drawings were made on squared paper, using a squared graticule in the eyepiece. These diagrams were chosen from a large number of specimens as representative of the average condition. They are here used only to help the description in the text and not as proof of the differences, which can only be obtained by examination of a large number of stained slides.

Comparing T/63 with Twort it is seen that in T/63 all the spaces between the blood-vessels are closely packed with cells, whereas in Twort connective tissue spaces, free of tumour cells, are to be seen. In other words, the masses of tumour cells around the blood-vessels are larger, deeper, and denser in T/63 than they are in Twort. The same holds good when J.R.S. and slow sarcoma are contrasted; the area of cells per blood-vessel is larger in J.R.S.

It is now possible to suggest why the blood-supply of fast-growing tumours, with cells abundantly and closely packed around the blood-vessels, is especially interfered with by radiation. I have shown³ that the nuclei of cells swell to about three times their normal size (superficial area) on about the second or third day after irradiation. This increase in bulk must take place at the expense of and bring pressure to bear upon surrounding tissues and structures. Thus capillaries and veins will be pressed upon, and in fast-growing tumours where the intervascular spaces are closely packed with tumour cells this will take place to a greater extent than where the tumour cells are less closely packed, as in slow-growing tumours. According to these findings, therefore, the rate of growth is not primarily the determining factor; it is because closely packed cells are commonly found in fast-growing tumours that these are especially susceptible to irradiation.

The radium used in these researches was on loan from the Medical Research Council. I am indebted to Dr. J. A. Murray, of the Imperial Cancer Research

Fund, for the supply of the tumours used in these researches.

ADDISON'S ANÆMIA:

THE EFFECT OF TREATMENT ON THE INTESTINAL INFECTION.

By F. A. KNOTT, M.D., M.R.C.P., D.P.H. LOND.,
HEMATOLOGIST TO GUY'S HOSPITAL.

So many excellent ætiological reviews of Addison's anæmia have recently been published, notably those by Hurst,¹ Davidson,² and Davidson, McErie, and Gulland,³ that very little repetition is necessary. For the purpose of this note it may be emphasised that consistently good results are being reported as a result of liver treatment and that all observers are now agreed upon the constant presence of complete achlorhydria and intense gastro-intestinal sepsis, particularly the development, by both descending and ascending infection, of a bacterial flora of faecal type throughout the whole length of the small intestine. As Davidson remarks, if auto-intoxication does not occur in pernicious anæmia it can never occur at all. Any acceptable ætiological theory of the disease must recognise both these factors, and in recent times much attention has been devoted to their reconciliation. Below are recorded a few bacteriological observations, made before and after treatment, in the hope that they may, of themselves and from comparison with the work of others, prove helpful in clearing up this most difficult problem.

During the past four years I have, whenever opportunity occurred, examined the gastro-duodenal and faecal bacteriology of proved cases of Addison's anæmia. The results obtained from 37 patients were published⁵ in January, 1927, and, after comparing my own results with others available at that time, I suggested that the reason for complete failure on the part of so many workers to isolate a specific bacterium in Addison's anæmia arose from the fact that there is no specific organism, the toxins being products in general of the grossly faecal flora which comes to occupy the small intestine. In the following year Davidson, after working on similar lines with 32 cases, suggested that it is unnecessary to state categorically whether the toxin is produced by one or all of the organisms present in such abnormal numbers and position, or even whether it is the result of bacterial action on the ingestion of food materials. This observer's detailed bacteriological results have just been published, and, after discussing them with him personally, I think I can safely say that our results agree in all essential particulars, except that I have recorded a somewhat higher incidence of hæmolytic strains of streptococci in the gastro-duodenal specimens, and of *Bacillus coli* in both the gastro-duodenal and faecal specimens. The former discrepancy is probably explained by the fact that several of the cases in my series suffered from relatively acute oral and upper alimentary sepsis. I found hæmolytic streptococci in the faeces in one case only, but I have concluded from further experiments that the coliform strains do not produce a true, separable hæmolysin, but, as Davidson suggests, cause rapid hæmodigestion in blood media. Therefore my figures for the incidence of hæmolytic strains of *B. coli* were probably too high. I entirely agree with the general finding by many observers that the anaerobic bacteria, many of which are hæmolytic in normal people, are markedly increased in the faeces in Addison's anæmia. A review of all the bacteriological facts so far established shows that in most of the cases the only organisms which can produce a free hæmolysin and are present in sufficient numbers to elaborate in the intestine enough hæmolysin to allow its absorption in any quantity,

are the anaerobic strains, particularly those which would be classified as *B. welchii*. But there are several reasons for hesitation in accepting this organism as the specific cause of the anæmia. For example, it has been my experience as well as that of several other workers on the subject that, as I pointed out when recording my first series of cases, the anaerobic increase does not especially concern the hæmolytic strains. When these faecal strains of *B. welchii* are isolated such extreme variations are found in the amount of hæmolyisin they produce that it is impossible to conclude that an increase in the number of *B. welchii* spores in a faecal specimen necessarily proves that the amount of free hæmolyisin in the intestinal contents is raised in corresponding proportion. Several other reservations are carefully discussed by Davidson⁴ in his most recent paper, and need not be detailed here. There is, I think, much to be said for his contention that bacterial hæmolyisins are not necessarily of ætiological importance in the disease, and that it is the gastro-intestinal sepsis generally which produces a toxic effect on the liver and prevents it from providing sufficient of that substance which appears to be essential for the proper maturation of the megaloblasts.

Bacterial Content of the Faeces.

The particular concern of the present note is, however, the effect of treatment. Since my original series was published a few more cases have come under observation and, more important, it has been possible to examine some of the original patients after their return to normal. In the first place, the bacterial content of the faeces was estimated before and after successful treatment by high liver diet. Table I.

For the detection of the highest dilution containing *B. welchii* spores, previously heated tubes of Robertson's cooked meat medium were used, 1 c.c.m. of the various dilutions being added, and, after heating to 80° C. for 20 minutes the tubes were closed with one-inch caps of vaseline and paraffin and incubated at 37° C. for several days. From those tubes which showed the characteristic *B. welchii* reaction subcultures were made into litmus milk tubes similarly capped and incubated

in order to obtain the characteristic clot. For the estimation of coliform bacilli plates of bile-salt agar were poured after adding 0.1 c.c.m. of each suspension examined.

The figures in Table I. agree in the main with the quantitative estimations of bacteria in the faeces of untreated cases of Addison's anæmia which were made by the observers already quoted, but they also emphasise one very important ætiological point—namely, that the faecal bacteriology is not altered as the result of liver treatment, and cases showing a return to a normal blood picture still retain their intestinal infection.

The results of the van den Bergh reaction applied to the serum are important in relation to the persistently high bacterial counts. In Cases 2 and 4 the originally positive indirect reaction remained, in spite of the relatively normal blood picture, and in Cases 1, 3, and 5 the reaction had quickly become completely negative after liver treatment was commenced and had remained negative up to the time that the bacterial counts were made. If the positive reaction be taken to represent active hæmolyisin, then hæmolyisin was still occurring in 2 and 4 but had ceased in the others. If the hæmolyisin depends upon the amount of absorbable hæmolyisin in the intestines, then one would have expected Cases 1, 3, and 5 to show a decided decrease in the intestinal infection, but this was not seen. The disappearance of the positive van den Bergh reaction does not necessarily appear to correspond with a period of reduced intestinal infection.

One would not, I think, expect liver taken by the mouth to influence directly any intestinal infection present, and that it cannot do so is suggested by the result of an experiment which I have carried out several times with slight modifications. Various liver preparations were incorporated in quantities varying from 0.2 to 2 per cent. in the usual agar and broth media used in routine bacteriological examination of faeces, control cultures being made in the same medium free from liver. No indication could be obtained that liver extract or digested liver had any appreciable influence upon the number of organisms growing in faecal cultures.

It seems safe to assume, therefore, that liver treatment has no direct influence on the intestinal infection which all observers agree exists in Addison's anæmia. On the other hand it is possible to reduce to some extent the concentration of bacteria in the intestines by systematic attack upon all the factors which give rise to and maintain this infection—e.g., buccopharyngeal and dental sepsis and achlorhydria. In support of this it may be of interest to mention the findings in two cases of Addison's anæmia which came under observation early in 1924, before the introduction of treatment by high liver diet, in whom

systematic eradication of septic foci, administration of dilute hydrochloric acid by the mouth, and a long course of *B. acidophilus* milk produced gradual recovery to a normal blood picture, which has been maintained. At that time only quantitative examinations of the total number of coliform bacilli in the faeces and the relative number of streptococci to coliform organisms on plates were made. In both cases the bacterial counts were noted to fall quite definitely. It is unfortunate that anaerobic counts were not also made. The evidence of only two cases is, of course,

inconclusive, particularly in such a disease as Addison's anæmia. Whatever reduction in intestinal infection occurred, however, was evidently due to direct attack on the septic factor in the disease.

That this septic factor may be present without producing actual anæmia is clear from the figures in Table III., which records the faecal bacteriology in three other cases of complete achlorhydria.

In each of these cases the gastric germicidal barrier was entirely absent, as is seen from the high counts of the organisms in the faeces, but the blood picture was quite normal. In short, the intensity of the intestinal toxæmia must evidently exceed a certain level before anæmia begins to develop, which is a good reason for attempting, in those cases which are anæmic, to reduce the intestinal infection by direct means, in spite of the fact that they may, as far as the blood picture is concerned, show a good response to liver treatment.

The cases in Table I. have retained their high bacterial counts in the faeces throughout an apparently successful course of liver diet. In the past it was common to produce prolonged remissions of the anæmia simply by reducing the intestinal infection and improving the patient's general condition. It is, then, but a short step to the suggestion that Addison's anæmia may be influenced in two entirely different ways, because there are two distinct factors concerned. The bacteriological facts seem to be entirely in accord with the theory that liver treatment promotes regeneration of normal blood cells from the flagging bone-marrow, and presumably augments the supply of some marrow-activating liver-derived substance normally present in the circulation. If sufficient regenerative response is obtained the influence of the intestinal toxæmia may be entirely overshadowed. On the other hand, in a certain number of cases where the bone-marrow is not too exhausted to recover of itself, a small reduction in the intestinal toxæmia may just sway the balance sufficiently to allow the regenerative phase to be established. In short, in Addison's anæmia we may have a relatively delicate balance between the natural reproductive powers of the bone-marrow (which are in turn dependent upon an adequate supply of liver substance) and a toxæmia. It is possible to produce a normal blood picture in nearly all cases by stimulating the former by liver treatment, and in a smaller number, perhaps those of shorter history, by reducing the intestinal infection sufficiently to allow the bone-marrow to recover.

Recent clinical reports all agree that the nervous lesions in patients showing signs of subacute combined degeneration of the cord appear to be uninfluenced by liver treatment. That the bacterial content of their faeces is high, whether they are anæmic or not, can readily be demonstrated. For example, Case 5 in Table I. and Case 1 in Table III. are brothers, both with complete achlorhydria. The first showed a hæmoglobin percentage of 30 with a typical blood picture of Addison's anæmia; the second had definite signs of subacute combined degeneration of the cord, but his blood picture was absolutely normal. Liver treatment was entirely successful in the former, his hæmoglobin rising steadily to 90 per cent., but was without effect upon the nervous symptoms of the latter who, however, showed signs of improvement under systematic direct attack upon his alimentary sepsis. From cases of subacute combined degeneration of the cord under his care, Dr. Hurst has been kind enough to show me several instances in which progress of the cord lesions has been arrested in this way and

others in which undeniable improvement has occurred. Evidently it is possible, by reducing the intestinal bacteria, to influence favourably the cord lesions as well as to relieve to some extent the exhaustion of the bone-marrow, but liver treatment is effective for the latter purpose only. Therefore in all cases showing signs of cord involvement it is especially important to attack the septic element directly, as well as instituting liver treatment if anæmia is present.

Conclusions.

Evidence is given that liver treatment does not influence the intensity or the nature of the intestinal infection in Addison's anæmia, that the disappearance of the positive indirect van den Bergh reaction does not necessarily correspond with a reduction in the intestinal infection, and that cases in which return to a normal blood picture has occurred may still show just as high a bacterial content in the faeces as when in the acutely anæmic stage.

To prevent remissions, therefore, the necessity of treating the alimentary sepsis directly as well as administering liver is emphasised, and some bearings of the bacteriological facts upon the possible ætiology of the disease are briefly discussed.

Clinical and Laboratory Notes.

THE

ADRENALIN TEST FOR THYROTOXICOSIS

BY LAMBERT ROGERS, F.R.C.S. EDIN.,

ASSISTANT IN THE SURGICAL UNIT, WELSH NATIONAL SCHOOL OF MEDICINE.

Gross deviations of thyroid function in the direction, on the one hand, of hyperactivity with the possibility of perversion, and on the other of insufficiency have long been recognised. Both cretinism and exophthalmic goitre were noticed before 1840; myxædema was described by Sir William Gull, of Guy's, in 1873, and shortly afterwards named by Ord, of St. Thomas's, and cachexia strumipriva was defined by Kocher in 1882. Lesser degrees of thyroid perversion, however, were not recognised until recently, and even now are frequently overlooked. The well-known signs are increased basal metabolism; tachycardia; thyroid enlargement; vasomotor disturbances, pallor alternating with periods of flushing and free perspiration, feeling of heat, mental acuity, perhaps irritability or delirium; tremulousness, especially in the outstretched hands; diarrhoea; glycosuria and lowered sugar tolerance; low blood pressure; vomiting; sleeplessness; loss of weight; pigmentation, and exophthalmos, all of which are only present in cases of very toxic exophthalmic goitre. In less toxic cases, and especially in other varieties of thyrotoxicosis, these may be present in part only or may be only evoked by arduous exertion, some intercurrent disease, or an emotional shock. The basal metabolic index may serve to distinguish incipient cases of thyrotoxicosis, but basal metabolism estimations have certain disadvantages, the chief of which is the wide limits of error in making the estimation, the result being appreciably affected by the nervousness of the patient. Other disadvantages are discomfort to the patient, whose exogenous metabolism must be reduced to a minimum by starvation, and the expense of the necessary apparatus. To avoid these difficulties search was made for a clinical test which would be simple, safe, and easy to perform, and since the sympathetic nervous system in thyrotoxic patients is hypersensitive to adrenalin.

TABLE I.—ADRENALIN REACTIONS IN GOITRE CASES.

No.	Sex.	Age.	Type of goitre.	Pulse-rates.			Blood pressure mm. Hg.			Result.	Remarks.
				Mean before adrenalin.	Mean after adrenalin.	Increase or decrease.	Mean before.	Mean after.	Increase or decrease.		
1	F.	53	Exophthalmic.	131	170	+39	137.5	163	+25.5	Positive.	Tremors appeared, epigastric pulsation and transient auricular fibrillation.
2	M.	49	Cyst in left lobe. Mild hypothyroidism.	93	84	-9	120	106	-14	Negative.	—
3	F.	19	Endemic goitre. Scabard trachea. Mild thyrotoxicosis.	79.3	112	+33.3	111	126	+15	Positive.	Felt her heart beating.
4	F.	48	Suppurative thyroiditis. Thyrotoxicosis.	132	160	+28	138	139.6	+1.6	Positive atypical.	Tremors developed. Extra-systoles noted.
5	F.	33	Multiple adenomata. Mild thyrotoxicosis.	81	111	+30	133	132	-1	Positive atypical.	Tremors elicited.
6	F.	29	Graves's disease.	120	160	+40	117	148	+31	Positive.	Felt hot. Tremors became coarser.
7	F.	26	Adeno-parenchymatous.	86	111	+25	128.5	131.5	+3	Positive atypical.	—
8	F.	43	Adeno-parenchymatous. Toxic.	103	121	+18	123	128	+5	Positive atypical.	Felt heart palpitating. Tremors elicited.
9	F.	41	Multiple adenomata. Toxic.	91	114	+23	168	189	+21	Positive.	Pulsation of carotids became visible.
10	F.	17	Multiple foetal adenomata.	80	90	+10	93.5	95.6	+2.1	Negative	—
11	F.	44	Adeno-parenchymatous. Mildly toxic.	100	105	+5	127.5	136.5	+9	Positive.	Fine tremors appeared in outstretched hands.
12	F.	63	Adeno-parenchymatous. Toxic.	100	130.5	+30.5	144.5	165	+20.5	Positive.	Tremors appeared. Perspiring freely. Pulsation of jugulars noted.
13	F.	28	Foetal adenoma (right lobe). Breaking down in centre.	71.2	84.4	+13.2	97.4	109.9	+12.5	Positive.	—
14	F.	47	Multiple adenomata.	76.8	82	+5.2	114.4	120	+5.6	Positive.	—
15	F.	58	Multiple adenomata. Old standing (?). Early malignant change.	82.4	75.6	-6.8	123.4	119.8	-3.6	Negative	—
16	F.	20	Exophthalmic.	121.6	149	+27.4	113.6	160.4	+46.8	Positive.	Tremors became coarser; felt heart palpitating; became anxious.
17	M.	25	Exophthalmic.	101	106.8	+5.8	132	141.8	+9.8	Positive atypical.	—
18	F.	18	—	91	94	+3	116.5	116.6	+0.1	—	No tremors. No subjective symptoms.
19	F.	26	—	87	87	..	121	113	-8	—	Coarse tremor in left hand. No subjective symptoms.
20	F.	19	Adeno-parenchymatous.	95	104	+9	123	120	-3	—	—

* Ten minutes after injection præcordial and carotid pulsation present, and tremor in right hand somewhat exaggerated. Very marked exophthalmos, but cardiovascular features in abeyance. While under observation, pulse was not above 110 at any time.

the adrenalin reaction introduced by Emil Goetsch was tried and in a slightly modified form was found to be very effective.

The Adrenalin Test.

In 1916 Levy¹ showed that in cats an injection of adrenalin raised the systolic blood pressure very considerably if the cervical sympathetic were stimulated at the same time, whereas when this nerve was not stimulated the rise was not nearly so great. The rise did not occur if the thyroid had been previously extirpated, and it was concluded therefore that the secretion of this gland sensitised the sympathetic to the effect of adrenalin. In man many of the signs and symptoms of thyrotoxicosis can be exaggerated in a frank case or rendered apparent in an incipient one by adrenalin injections.

Goetsch,² of Long Island College Hospital, Brooklyn, applied these facts clinically, and in 1918 described an adrenalin test, the result of which is regarded as positive if, after subcutaneously injecting 0.5 c.cm. of fresh 1 in 1000 solution of adrenalin hydrochloride, a rise in the pulse-rate of 20 or more beats and in the systolic blood pressure of from 10 to 50 mm. of mercury occurs within five minutes of the injection. Various degrees of positivity occur.

The Adrenalin Test of Goetsch, Slightly Modified.—The test has been performed in a slightly modified

TABLE II.—Adrenalin Reactions in Healthy Subjects.

No.	Sex.	Age.	Pulse-rates.			Blood pressure (mm. mercury).			Result.
			Mean before adrenalin.	Mean after adrenalin.	Increase or decrease.	Mean before.	Mean after.	Increase or decrease.	
1	M.	52	88	80	-8	131.6	125	-6.6	Neg.
2	M.	26	125	69	-56	112.5	108	-4.5	"

6	M.	21	81	83	+2	130.5	126.5	-4	"
7	F.	33	93	91	-2	109	108	-1	"
8	F.	33	97	95	-2	116	110.5	-5.5	"
9	F.	24	89	88	-1	117	111.5	-5.5	"
10	F.	20	93.5	100	+6.5	120	123	+3	"

* Sl. pos., slightly positive.

There was clinical evidence of slight thyroidism. Subjects 5, 7, 9, and 10 felt heart beating about five minutes after the injection, and 7 developed a slight tremor.

form from that originally introduced by Goetsch, and is carried out as follows:—

The patient, who is resting quietly in bed, has the test explained to her and is assured that there will be neither danger nor pain. The pulse-rate and systolic blood pressure are taken at short intervals until constant, and a mean is obtained. 0.5 c.cm. of a 1 in 1000 solution in normal saline of fresh adrenalin hydrochloride is then injected subcutaneously over the deltoid, and a further series of readings are taken up till 15 minutes later; at the

same time signs and symptoms are noted, since these may be evoked or exaggerated.

Tables I. and II. show the result of this test applied to a series of goitre cases and to a series of healthy students who volunteered for the purpose. It will be seen that in healthy subjects there is little or no response.

Objections to the adrenalin test have been raised, but most observers agree that when it is negative the patient is in all probability not suffering from thyrotoxicosis. In our experience a markedly positive result indicates definite thyrotoxicosis. The atypical results are more difficult of interpretation, but it has been found that where the reaction to the adrenalin test is severe, the reaction to operation on the thyroid is also severe. Hence the extent of the reaction to adrenalin gives an indication of the degree of post-operative thyroidism to be expected.

The value of the adrenalin test carried out according to the technique described may be summarised as follows: 1. It reveals the presence of incipient thyroidism. 2. It provides a rough estimation of (a) the degree of thyroid intoxication, and (b) the extent of the reaction which is liable to follow operation on the thyroid. 3. If the reaction is absent or negative, the goitre is not toxic, and there will be no post-operative reaction.

A NOTE ON ATYPICAL OR MILD ENTERIC.

BY EUSTACE THORP, O.B.E., M.B. BELF., D.P.H.,
DEPUTY MEDICAL OFFICER OF HEALTH FOR SUNDERLAND.

SOME months ago I reported¹ some curious cases that appeared to be of enteric nature, observed over about a year amongst so-called pneumonias and in small groups. One or two in each group gave a positive Widal to typhoid or paratyphoid B; the remainder were negative though clinically mild enterics, and their chief characteristic was a febrile attack of from 10 to 17 days' duration. On the return of the temperature to normal rose spots made their appearance and clinically the cases were diagnosed as enteric or paratyphoid B as the case might be. By the time the spots appeared the patient as a rule seemed to be convalescent. Blood tests were taken and in about one case in five came back positive in dilution of 1/50 and 1/125, the remainder being negative. The blood of other patients whose condition had been confidently diagnosed as enteric was examined with much the same results. I then tried repeated Widal reactions and had the satisfaction of finding that, like the rash, the reaction appeared to be delayed, positive results being obtained as late as the thirty-ninth day when the patient was quite well and would in the ordinary way have been discharged from hospital had we relied upon the Widal test to exclude enteric.

These cases were sent in as "pneumonia" or "observation pyrexia," and inquiry would frequently demonstrate a previous case of pneumonia with which the patient had been in contact. Usually there were few signs in the lungs, but the pyrexia had remained present rather long. It subsided shortly after admission and the patients were able to get up. Then it was found that they showed typical lenticular rose-pink spots which led to investigation of the blood. Much has been said lately about the laboratory being a bad master, and I think the above cases show that clinical evidence of enteric is essential and that a negative Widal does not exclude the disease, particularly in the mild forms.

Cases in my series have alternated, suggesting a vacillation in the presence of the reaction. To-day, I am afraid, the clinical diagnosis of enteric is often washed out on a single negative Widal. I suggest

that it is cases such as the above that keep enteric going as much as the suspected but often untraceable "carrier," and if so the mystery of the sporadic case may not always be so elusive. The Widal seems to have but a small margin of error in well-marked clinical cases, but mine show that the margin of error in very mild cases is much greater and that laboratory confirmation involves several tests.

I publish these notes principally to correct a fallacy perpetuated in text-books that there is little error in Widal reactions. To-day this applies, I feel sure, only to the well-marked clinical case. In the mild forms of the disease the reaction is often delayed, and many cases like those I have described do undoubtedly exist. I have always suspected that these mild infections could be found among the "pneumonia" notifications at periods when sporadic cases were appearing and that they are missed both inside and outside hospital. On watching them the spots were found to appear during apparent convalescence; the Widal test was negative and the patients were discharged. Later they were detained and further Widal tests proved positive. All the cases were easily diagnosed clinically as enteric or paratyphoid before the first Widal test was made.

NOTE ON THE TREATMENT OF ASTHMA IN CHILDREN WITH TUBERCULIN.

BY T. M. LING, B.M. OXF.,
JOHN AND TEMPLE RESEARCH FELLOW IN DISEASES OF
CHILDREN, ST. THOMAS'S HOSPITAL.

WITHIN the last few years considerable interest has been reawakened in the treatment of asthma with small doses of tuberculin, the credit for this being due primarily to W. S. van Leeuwen, of Leiden.

In 1897 Bussenius¹ obtained encouraging results with tuberculin treatment in a patient suffering from asthma and pulmonary tuberculosis, and in 1913 Frankfurter² published seven cases of asthma treated in a similar way, all of whom did well. Since then Bouveyron,³ Bonnamour and Duquaire⁴ in France, and Nelson⁵ in England have shown promising results. Van Leeuwen,⁶ working with a large series, claims that about 50 per cent. are almost completely cured, about 25 per cent. are improved, and 25 per cent. are uninfluenced. Most of the patients so treated have been adults and therefore it was considered to be of interest to try the effect of this treatment on children. Twenty-four asthmatic cases were therefore chosen from the children's out-patient department at St. Thomas's Hospital, all of whom had been receiving treatment for not less than two years, while many of them had had symptoms for a considerably longer time. The treatment that had been given previously was potassium iodide by the mouth and injections of adrenalin during the attacks, while any source of infection in the mouth or nasopharynx had been eradicated.

As a preliminary measure all the cases were examined clinically and radiologically to exclude as far as possible pulmonary fibrosis and enlarged mediastinal glands. Some of the French literature recently has suggested an association between congenital syphilis and asthma and consequently all the cases were examined with this point in view; no suggestive clinical signs were found and the Wassermann reaction was negative in every case. The average age of the patients was 7.5 years.

Cutaneous Pirquet reactions were done in all cases and 45 per cent. gave definitely positive reactions. Quite recently Baagoë⁷ published the results of the test on a much larger series of asthmatic children, and found that only 32 per cent. gave positive reactions. The treatment appeared equally efficacious, whether the cutaneous reaction was positive or negative.

¹THE LANCET, 1928, i., 371.

Method of Treatment.

In all cases Old Tuberculin (Burroughs Wellcome and Co.) was used and injections were given subcutaneously once a week. As the children were out-patients, it was not feasible to see each case on the day following the injection, but the mothers were instructed to note any general or local reaction that occurred; 355 injections were given and a general reaction was noted in two cases, while a history of a definite local reaction was given in five cases.

The usual procedure was to start injections with 0.1 c.cm. of a dilution of 1 in 1,000,000 and increase the dose on each occasion by 0.1 c.cm. or 0.2 c.cm. until 0.1 c.cm. of a 1 in 100,000 dilution was reached. Beyond this the dose was increased very gradually until the optimum quantity was found for each individual case. When once the correct quantity is obtained, it is not advisable to increase the strength of the injection as an attack of asthma is liable to be brought on. On two occasions this occurred within an hour of the injection, where the strength had been increased unduly quickly.

Two separate courses of treatment have been given with an interval of two months. Naturally the individual attendances were sometimes irregular, but for the whole group it was excellent, and the willingness and enthusiasm with which the mothers brought up the children week after week is probably the best indication of the efficacy of the treatment, particularly as each injection necessitates a certain amount of pain for the child. The average number of injections in the first course was 15 and in the second 10; thus it can be seen that the treatment takes a considerable time.

Results.

Of the original 24 cases, three were unaffected by the treatment and were discharged, while two discontinued treatment as they left the district. The remaining 19 had regular treatment, with occasional weekly lapses owing to intercurrent illness, and are all improved. The word "cure" admittedly should be used with greater caution than usual in asthma and only two cases could be included under this heading. The remaining 15 cases remained practically free from symptoms while under treatment, but lapsed to a varying degree between the courses and since treatment was discontinued. In asthma the patient's symptoms are the only index of the severity of an attack, and in every one of these cases the mother was emphatic that the attacks were much less severe and less prolonged than previous to treatment. A careful record was made in each case of the average interval of freedom from attacks previous to treatment and subsequent to the latter this interval has been increased by approximately 30 per cent.

Conclusions.

Admittedly the results are not striking and do not harmonise with van Leeuwen's claims that 50 per cent. of cases are curable by this means. On the other hand, it is justifiable to state that the frequency and the intensity of the asthmatic attacks can be diminished and this in itself is a justification for a more extended trial and for the inclusion of tuberculin among the methods of treatment of the established disease.

I am indebted to Dr. R. C. Jewesbury for permission to publish these cases.

JOINT TUBERCULOSIS COUNCIL.—At a meeting of the Council, held on Oct. 17th, Dr. H. G. Sutherland reported on the recent International Tuberculosis Conference at Rome. Some of the posters exhibited there were, he thought, too terrifying to achieve useful purpose. Dr. G. Lissac, for example, presented a statistical study on *The Fate of Young Children in Tuberculous Households*, dealing with a total of 1923 children up to 5 years, the figures being controlled by standard modern statistical methods. This study revealed that the number of deaths from non-pulmonary tuberculosis in young children exposed to infection from pulmonary cases was some ten times as great as that of the controls.

Medical Societies.**ROYAL SOCIETY OF MEDICINE.****SECTION OF OTOTOLOGY.**

Mr. SOMERVILLE HASTINGS took the chair at a meeting of this Section on Nov. 2nd, and delivered a Presidential address on the

Estimation of Hearing Capacity.

Reviewing the progress of otology during the last 25 or 30 years he could not help feeling, he said, that our comparative ignorance of the pathology and treatment of so many cases of deafness of both the middle and internal ear types was partly due to the methods of examination used in the past. The hearing capacity, judged by the distance at which a whisper, the conversational voice, a watch, or Politzer's acoumeter could be heard, though of value clinically, were quite useless for scientific purposes. It was necessary at least to have a relatively pure sound such as that produced by a tuning-fork or a wireless valve; in the audiometer shown to the Section by W. S. Tucker and himself in 1923 the source of sound was a wireless valve, but the estimation of hearing was by means of purely arbitrary units. Harvey Fletcher estimated hearing capacity in what he called sensation units, such a unit being the minimal change in the intensity of a sound perceptible to the normal ear, but this did not go very far. What the speaker wanted to know before he could form a correct mental picture of a given case of deafness was, for every pure note between the upper and lower limits of audition, the percentage of normal hearing that remained. If it was also possible to estimate in percentages the degree to which the cochlear nerves and cerebral centres were functioning, the observer could say exactly to what extent the deafness was due to changes in the conducting apparatus and to what extent in the perceptive. Supposing, for example, it was found that a patient had 25 per cent. normal hearing when tested by air conduction, and say 50 per cent. normal hearing when his perceptive function was tested, then it could be said that he had only $\frac{25}{50} = 50$ per cent. of normal hearing by conduction, or, in other words, that owing to impairment of the conduction of sound waves only 50 per cent. of the waves passing through the external and middle ear of a normal individual and reaching the cochlea were able to pass through his.

The President was convinced that for scientific study of deafness it was essential to give up arbitrary units of hearing and try to discover what percentage of the normal power of conduction and what percentage of the normal power of perception were present for pure sounds of the principal wave-lengths. That was the problem to be solved, and it was not an easy one.

He proposed to consider first the principles involved in estimating the perceptive function. It must be evident that the ordinary method of estimating bone conduction by means of a vibrating tuning-fork placed upon the mastoid was open to a thousand fallacies, since the more complete the interference with conduction through changes in the external or middle ear the longer would the sound of the tuning-fork be heard. In November, 1917, a committee of the Section formed to organise otological research had issued a report whose most useful recommendations, he thought, were those concerning hearing tests. Coming at a time of great national stress, the report had not received the attention it deserved. One of the tests therein recommended was that described as "absolute bone conduction." To carry out this test the observer (who presumably had normal hearing) and the patient each blocked his external auditory meatus with his finger, preferably by pressure on the tragus. A vibrating tuning-fork was then alternately pressed on to the mastoids of the patient and observer until it was no longer heard, and in this way the bone

conduction of the two persons was compared. Ever since the publication of the report the speaker had made use of this test in every case of deafness that he had at all carefully investigated, but so far he had never found absolute bone conduction increased above the normal. The oft-repeated statement that in otosclerosis bone conduction was increased was therefore untrue if it was applied to absolute bone conduction. If the comparison between the bone conduction of the patient and observer, with the meatus unblocked; was referred to, then admittedly in so-called otosclerosis bone conduction was increased. But so it was in all other forms of conductive deafness, whatever injury or disease of the external or middle ears was their cause. Indeed the increase of bone conduction as thus tested in the most advanced case of otosclerosis conceivable could not be greater than it was when a normal ear was thoroughly obstructed by a plug of wax.

Obstruction of the meatus in the absolute bone conduction test increased the perception by bone conduction very considerably. Therefore, if the degree of perceptive hearing (bone conduction) in the two ears was approximately equal, however great the degree of conductive deafness in the ear not being examined, the test would not be vitiated by it. Difficulties would only arise where there was marked perceptive deafness on the side being tested, with good cochlea hearing and considerable conductive deafness on the other side—an unusual combination. In such cases the patient would usually say at once that he was hearing the tuning-fork in the opposite ear, and it would be easy to exclude the ear not being tested, either by means of a noise machine (Bárány's box), or by rapid movement of the finger in the meatus. Lowndes Yates, T. A. Clarke, and others had shown that the total hearing (perceptive and conductive) power of a patient for C2 and other tones could be estimated as follows:—

A tuning-fork is held at any constant distance from the patient's ear. When he ceases to hear it is transferred to a similar distance from the ear of an observer who has normal hearing, and the time noted until it becomes inaudible. This gives the deficiency in seconds of the patient for the note in question. By means of a table or graph this can be converted into percentage retention of "normal hearing distance," and seeing that the intensity of sound varies inversely as the square of the distance from its source, the square root of this figure gives the percentage of total hearing power present.

By means of the absolute bone conduction (A.B.C.) test it was possible to estimate the percentage of normal perceptive (cochlea) hearing retained by a patient. A vibrating tuning-fork was held on the patient's mastoid with the meatus closed until perception of sound ceased. It was then transferred to a normal ear and the time noted until the perception of sound by air conduction ceased. By means of the table referred to above this was translated into percentage retention of normal hearing distance (N.H.D.). If not already known, a similar observation was made with regard to the absolute bone conduction of a person with normal hearing; then the formula—

$$\frac{\text{Percentage retention of N.H.D. for patient's A.B.C.} \times 100}{\text{Percentage retention of N.H.D. for normal A.B.C.}}$$

gave the percentage of perceptive hearing present. Knowing, then, the percentage of total hearing present in a given case and also the percentage of perceptive (cochlea) hearing it was easy to determine to what extent, if any, the deafness was due to changes in the conduction (external and middle ear) apparatus.

It might be objected, said the President in conclusion, that such methods as these were laborious and crude, and moreover uncertain because the personal equation of two individuals was involved. He knew of no other method, however, that would tell him what he wanted to know. He was also sure that neither investigations regarding otosclerosis nor any other similar researches would really prosper until methods of testing ears and estimating hearing capacity had been standardised. The last attempt

made by the Section of Otology had been by a committee set up in 1917 at a period when few were able to give much time or attention to the subject. Was it not time that the Section made another attempt to solve this important problem?

Dr. KERR LOVE (Glasgow) read a paper entitled
A Classification of Deafness Based on the Effect of Deafness on Efficiency.

He said he approached the subject from the standpoint of the capacity of the deaf person. He invited a comparison between the child of 5 years with normal hearing and one of the same age who was born deaf. The former was full of life and chatter, with a small but increasing vocabulary, whereas one felt helpless in attempts to amuse the deaf child. It took ten years of special education to equip the deaf child for any walk in life, and at the end of that time his choice of an occupation was restricted. Dr. Love submitted four subdivisions: (a) Cases in which the deafness was congenital, including a small proportion in which the cause was congenital syphilis. Mostly these cases had some island of hearing in their deafness. (b) Mute, or semi-mute. In the matter of capacity these did not differ materially from the first class. They might have to go into special schools for the deaf. Usually the deafness was total, and may have been due to cerebro-spinal fever or to syphilis. (c) Those who had become deaf after the speech habit had been well established. Generally here, too, the deafness was total, but owing to speech having been acquired in childhood the outlook in regard to usefulness and enjoyment was superior to that of the child born deaf. The basis of the teaching was the substitution of one sense for another. (d) The partially deaf, the largest and the most hopeful class, and one which came within the scope of hearing tests. If a person could hear the whispered voice at the distance of 20 ft. he was not likely to rest under any employment disability or handicap; but if a child could not hear whispered speech at 6 ft. he could not profitably remain in the ordinary class of an elementary school.

Dr. Love advocated four practical measures. The first was an intensive campaign against aural disease in children. The second was an intensive study of otosclerosis with the view to prevention. Thirdly, he favoured compulsory notification of cases of congenital syphilis; and lastly he would have the public educated about the causation of congenital deafness. Congenitally deaf people should not be allowed to marry into families having a like disability.

Dr. T. A. CLARKE (Canterbury) read a paper on
Hearing Tests.

He passed over the subject of the testing of the upper and lower limits, especially as the present methods of testing for these were fairly satisfactory. In performing Gellé's test one noted, he said, any change in the perception of bone-transmitted sound occurring during the alteration of air pressure in the meatus. Gellé supposed that increased pressure in the meatus caused inward movement of the drumhead, ossicles, and the footplate of the stapes, so causing a rise in the intralabyrinthine pressure, with consequent lessened sensitivity of the cochlea; that fixation of the stapes would prevent such a sequence and there would be no variation of perception. This view, Dr. Clarke considered, was untenable, though the actual significance of the Gellé test was not yet known. With regard to tests dependent upon perception of tuning-forks by air and bone conduction, these were the Rinne, the Schwabach, the Weber, and the Bing tests. Only the last of these needed explanation. In carrying it out the base of the tuning-fork was placed on the mastoid. When perception ceased the mastoid was occluded. If the fork then became audible Bing was said to be positive. These tests were important in making a functional diagnosis, and he considered it was their shortcomings which were responsible for the present unsatisfactory state of aural diagnosis. The fundamental reason for their

failure was that the result was influenced by changes in both conductive and perceptive functions, and therefore the result could be indicative of neither.

Physiologically, hearing power was the sum of the conductive and perceptive functions. The primary determination of the conductive function was difficult, either by subjective or objective methods, though Bing's test might provide an approximate indication. But the perceptive component could be accurately assessed by a comparison of the patient's absolute bone conduction. The test consisted, as the President had said, of the perception of a tuning-fork placed on the mastoid, the meatus being closed by the finger, and compared with the normal person's absolute bone conduction. In doing the test the tuning-fork should be raised and lowered, rather than kept in constant application, as fatigue might render the result unreliable. As soon as the patient ceased to hear the fork it was transferred to the tester's own mastoid and the meatus was closed. If the patient had no perceptive disorder there was no after-perception by the normal ear.

Dealing next with quantitative tests, Dr. Clarke said that one might express the hearing defect in arbitrary units, what the Americans termed "sensation units," or in intensity units, or on a hearing-distance basis. The last of these, in the speaker's view, was the best. It had been the custom to consider hearing, deafness, and the loudness of sounds in terms of distance. In practice the voice was an impossible agent in this connexion. Both the watch and the acoumeter were useful for testing hearing capacity in the matter of noises of high pitch. Electrical audiometers were valuable for research, but were not clinically practicable because of their complication, lack of portability, and cost.

Dr. Clarke concluded by describing his own procedure in testing, after which the three papers were discussed together.

In the discussion which followed, Mr. O. POPPER said that nobody had yet suggested a unit which everybody accepted; probably the President used one which was arbitrary. He agreed that absolute bone conduction was the only reliable test obtainable with the tuning-fork. He asked what means were adopted for ensuring that the tuning-fork was maintained at a constant distance from the ear. Also, could one always assume that the examiner's ear was normal? His criticism was that two systems were introduced—those of distance and time.

Sir JAMES DUNDAS-GRANT said that in carrying out tuning-fork tests there were many details, not brought out in the present discussion, which the thoughtful practitioner would have in mind. One was the factor of weight in the fork. A heavy fork was not calculated to give very satisfactory results for bone conduction. He agreed that the middle C (256 double vibrations per second) was the best fork to test with, but even forks of that note varied.

Mr. F. J. CLEMENSON regarded the Rinne test as entirely unnecessary.

Mr. ALEX TWLEDIE considered that Dr. Love's classification was a remarkably good one for educational purposes. But with regard to the 20 ft. whispering distance the speaker thought this should rather be taken as an arbitrary line between children requiring special treatment and children needing education in ordinary schools.

Mr. G. J. JENKINS said that for a long time the Bing test had been his great stand-by in arriving at an estimate of a patient's bone conduction. If one sounded a tuning-fork and then interfered with the low tones the high tones would be heard less distinctly. The great difficulty in measuring the hearing capacity with tuning-forks was to place the fork in the same position and at the right angle in each case. The least twist of the fork caused an appreciable difference.

Mr. A. J. STOLY (National Institute for the Deaf) complained that at present one found children with all kinds of history and all degrees of deafness planted in the same school, often in the same class. The Institute wished to get a terminology of deafness which

was based on the history and the degree of deafness, and which was intelligible to the ordinary teacher as well as to the medical practitioner. Dr. Love's classification would be very helpful in recommending to parents how best the child could be properly taught.

Mr. A. R. SHARPE (Leeds), speaking of his connexion with a deaf-and-dumb school, said Dr. Love's classification was a very sensible and sound one. One type met with was he who was truly mute, but was not a deaf-mute; he would apply to these the term "pseudo-deaf-mute," a child who heard but neither understood nor spoke, probably because of some fault in the cerebral system, such as auditory aphasia.

The openers replied briefly, and the Section then proceeded to the discussion of clinical cases.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN.

At a meeting of this Section on Nov. 5th Dr. F. J. POYNTON, the President, took the chair, and a paper was read by Dr. L. S. T. BURRELL on

FIBROSIS OF LUNG.

As many chronic pulmonary diseases began during childhood it was important, he said, to recognise and treat the various catarrhal conditions found at that period. Tubercle of lung was uncommon in infants, except as part of a general tuberculosis. During the first few years of life the mortality from tubercle was high, but afterwards it fell rapidly, until at the period between the seventh and sixteenth years it was very small. After 16, however, the mortality from the disease rose, reaching its maximum round about the fiftieth year; the mortality varied in different countries. There were three age-groups which could be usefully recognised in regard to tuberculosis: (1) the first five years of life, when general and surgical tuberculosis was common, pulmonary tuberculosis rare; (2) from 7 to 16 years, in which all forms of tuberculosis were rare; and from 16 to middle age, when the disease became more common, but was of a different type from that displayed by the child, in the savage, or in the inoculated guinea-pig. Tuberculosis of glands at the root of the lung was often present in children, but his experience had been that it was exceptional for the tissues of the lung to become subsequently infected. Therefore when one encountered a child with signs of tuberculosis in the glands of the chest there was no real reason for supposing that he would have pulmonary tuberculosis. Dr. R. C. Wingfield, at Frimley Sanatorium, had examined 160 hardened specimens of the contents of the thorax of children who had died from various causes in St. Thomas's Hospital, and had found macroscopic evidence of tuberculosis in the glands at the root of the lung in 17½ per cent., an observation which microscopical examination had confirmed. In these cases of tuberculous bronchial glands the disease normally became arrested, leaving as a sequel calcareous glands but no pulmonary affection. In some of the cases the children were listless, poisoned by the tuberculous toxin, but often there was little evidence of impairment of general health. When a child's lung was infected, there was a tendency to activity and rapid spread. The early case in the child did not necessarily show tubercle bacilli in the sputum, and they were absent, too, in late stages when fibrosis had occurred. Still, if the child caught a definite cold or had an attack of bronchitis the bacilli could be found in the sputum. Before the fibrotic change the child had probably been running about and playing like other children. In the adult when there were signs at the apex of the lung it was assumed that their origin was tuberculous, and generally this was a correct assumption. But it could not be applied to children. On following up children who showed signs at the apex, or pneumonia, it was found that in a considerable proportion the behaviour was not that of tubercle. Hence in the case of a child with an acute apical lesion it was safe to give a better prognosis than could be given

for an adult in a similar situation. The kind of patient he was referring to was one who was suddenly taken ill with what was called pneumonia; the signs were at the apex of one lung only, but the condition did not settle down like a pneumonia, and after three or four weeks there was still a temperature, up in the evening, down in the morning. Eventually the temperature came down by lysis, and the signs disappeared. Was it tubercle? The tuberculin tests employed had, in his experience, the great disadvantage of being positive in many cases in which clinically there was no tuberculosis. A negative test was more valuable. If such a child had a tuberculous lesion, what had happened? Probably he had a small tuberculous infection, and then added to that was a fresh infection, giving a focal reaction. The same kind of thing could be seen in the adult. It was easier to understand the course if the second infection was caused by some organism other than the tubercle bacillus. His own feeling was that the majority of these cases of children who had an apical or other lesion which subsequently cleared up were non-tuberculous. Still, tuberculosis played an enormous part in the causation of fibrosis of the lung.

It was the catarrhal conditions which were so important, not only from the standpoint of the individual child, but also from that of his associates, especially in the same family. These led also to bronchiectasis. The main causes of catarrh in children were measles, influenza, whooping-cough, the chief of these being measles. In 1925 there were over 94,000 deaths of children under 15 years of age in England and Wales, and more than 20,000 of them were due to non-tuberculous respiratory diseases. For pulmonary tuberculosis the figure was 1500, and for other forms of tuberculosis 5000. It was very important that the non-tuberculous respiratory diseases should be recognised. And it might be expected that these non-tuberculous diseases would leave behind them fibrotic and other changes.

In lobar pneumonia there was an exudation which was as a rule completely absorbed when the patient recovered. It was the broncho-pneumonia following influenza and measles which caused destruction of bronchial membrane and lung tissue; there was healing by scar tissue, and the healing was not complete, cases of "unresolved pneumonia" being of this nature. Thus it must be remembered that it was the broncho-pneumonic type of disease which was accountable for the cases of fibrosis. In children who had repeated attacks of bronchitis it was often found that the same part of the lung was attacked in each illness; and this could not be dismissed as a coincidence. Usually—and this was important from the standpoint of prevention—these children who had frequent colds and bronchial attacks had brothers and sisters who were known to be "chesty." Therefore if the first case in a family were treated thoroughly, there would be a good chance of lessening the total incidence of the states under discussion. The damage present after the onset of bronchiectasis could not be repaired. Much could be done before the onset of fibrosis: all sources of infection, such as tonsils, teeth, the gastro-intestinal tract, should be treated; Dr. Burrell advocated the use of a vaccine (autogenous if possible), as in his view it was more useful in childhood than in adult life. The giving of a vaccine seemed, both in hospital and in schools, to lessen the incidence of catarrhal and bronchial colds. He started very gradually, using 0.1 c.cm., and working up to a dose which caused a reaction, but never going beyond 1.0 c.cm. Dr. Burrell had a great belief in a long holiday for these children, the place and circumstances varying somewhat with the particular child's temperament. They should be kept out of hot stuffy rooms, and should be under rather than over-clothed. Many such children had intestinal toxæmia too.

Another group, surgical rather than medical, was that in which fibrosis followed empyema. It was now treated in a special way surgically, and it did not therefore lead to the serious fibrosis formerly seen as a sequel.

Discussion.

Dr. A. G. MAITLAND-JONES thought it should be emphasised that tuberculosis was a somewhat rare cause of fibrosis of the lung in children. Some talked of a condition termed "epi-tuberculosis," and he would like to hear more about that. He referred to the kind of case in which a child came with what seemed to be pneumonia; the illness lasted one or two months, with a fever, and then the temperature fell to normal, and physical signs of dullness remained in one or other lobe, perhaps with some crepitations. The condition might be thought to be fibrosis, but after persisting for two, three, perhaps five months, the signs cleared up completely. Was it justifiable to say that fibrosis was present?

Dr. HILDA STOESINGER spoke of the lessons learned in following up consecutive cases of broncho-pneumonia and allied conditions admitted to the Royal Free Hospital. Repeatedly she had noticed that cases with symptoms of localised pulmonary catarrh were occurring every two or three weeks. In a large proportion of cases of both lobar pneumonia and broncho-pneumonia there was a family history of contact with others having respiratory disease. Of 32 consecutive cases of lobar pneumonia 22 had a past history of recurrent bronchitis or pneumonia, and 16 had a family history. Of 34 consecutive cases of broncho-pneumonia 19 had a past history (no statement in 3) and 17 had a family history. These figures pointed to the importance of carefully supervising all cases of pneumonia whose clinical course resembled that of lobar pneumonia. She raised the question of the value of X rays in the diagnosis of these conditions.

Dr. C. D. S. AGASSIZ, speaking of experience in an institution with 350 beds for tuberculous children, said he thought that pulmonary tuberculosis in children was not uncommon; he found that a third of the cases of the pulmonary form showed the bacilli in the sputum. Was it Dr. Burrell's experience that in fibrosis of the lung the signs were most marked at the base of the lung? He himself had found that they were. Sometimes both bases were involved; the signs cleared up quickly, but came back again.

Dr. H. E. A. BOLDERO spoke of the good work done for these children in infant welfare centres, and said he would like to hear more about preventive measures. It was easy to suggest an out-of-door life and isolation from cases of coryza, but it might be well to persuade mothers wholesale to agree to inoculation with serum.

Dr. J. WATT raised the question of what happened to children who had non-tuberculous fibrosis of the lung, as the condition was seldom seen in the adult. Did such children succumb in adolescent or early adult life? Did they or did they not develop bronchiectasis? Or was tubercle grafted on to their fibrosis?

Dr. A. G. PHEAR spoke of children who had very definite signs in childhood, but later lost those signs. He thought a case of slowly resolving pneumonia, seen for the first time, might easily be regarded as a permanent fibrosis or bronchiectasis.

Dr. G. A. SUTHERLAND held that it was quite exceptional for fibroid lung to end in bronchiectasis. Lobar pneumonia probably never led to fibroid lung; a large number of cases of the latter condition, in his experience, recovered. Fibroid lung seemed to be a local disease—i.e., one arising in the lung itself—and the pathologist could usually find several organisms, such as streptococcus, the *Micrococcus catarrhalis*, and the influenza bacillus. With children living the life they did in London it was not surprising that among the organisms found was the tubercle bacillus. His own view of the ultimate fate of children with fibrotic lung was a favourable one.

Dr. F. PARKES WEBER questioned whether typical recurrent attacks of clinically slight pneumonia had ever led to fibrosis of the lung; he was sceptical on the point.

The PRESIDENT said he supposed that, apart from rheumatism and tuberculosis, fibrosis of the lungs

was one of the most important of children's diseases. The way some of the cases recovered—even those with extensive fibrosis and displacement of the heart—was surprising. Perhaps the signs heard suggested that the lesion was more extensive than it actually was. He had seen the experimental work done by Mr. Morrison Davies and others in earlier days, and had been astonished to see how, after the phrenic nerve had been torn away and ribs resected, recovery took place up to a certain stage. He agreed about the fine preventive work being done by infant welfare centres, and about the frequency with which infection in one part of the lung lit up time after time with fresh catarrhal visitations. He had particularly wished to have the surgical aspect of empyæma discussed, as for a number of years he had been working at the avoidance of open operation for these cases, substituting for it some form of closed surgery. Seeing how damp and miserable were some of the homes of these children, the number of recurrent attacks of respiratory disease was not surprising. He was not a great believer in vaccines.

Dr. J. S. JOULE raised the question of diagnosis as between collapsed lung and fibrosis of lung, and asked whether investigations with lipiodol had been made.

Dr. BURRELL briefly replied.

HUNTERIAN SOCIETY.

At a meeting of this Society held at the Cutlers' Hall on Nov. 5th, under the presidency of Dr. A. WESTERMAN, a discussion on

THE DOCTOR ON THE STAGE

was opened by Mr. WILLIAM DEVEREUX, who said that doctors he had played on the stage always looked preternaturally wise and never knew what was the matter with the patient. Was that lifelike? In both professions all that was necessary was a good bedside manner, and a great deal depended on the audience. The actor took off his hat to the doctor because he was always willing to use his skill for nothing, night or day, in the service of humanity. He belonged to a profession that—whatever its rewards—would always be underpaid.

Lady SIMON (Miss Lena Ashwell) spoke of "The Doctor's Dilemma" as a fit companion to Shaw's latest book, "The Intelligent Woman's Guide to Socialism"; their value as a serious contribution did not amount to the row of pins mentioned in the book. There were many points of similarity between the drama and medicine. The University of London had now recognised the importance of drama in the life of the people by instituting a diploma of dramatic art. From recent papers in the examination for this diploma she selected the following as of interest to medical men:—

1. For the physician: "Discuss the significance of Aristotle's theory of catharsis."
2. For the alienist: "Discuss heredity as treated respectively in any Greek or modern play."
3. For the orthopaedic surgeon: "Give an account of the principal changes in boots and shoes from William the First to Elizabeth."
4. For the New Health Society: "Describe the method of preparing and the dishes served at a banquet given by (a) Richard II., (b) Cardinal Wolsey, (c) Charles II."
5. For the anatomist:—and she would ask any member of the audience who could answer it to raise his hand: "Explain the various mechanisms of the body whereby balance is maintained."

Team-work was vital to both arts: the production of a play required the co-operation of a large number of specialists in different lines, and on the stage there was also the all-round man who played in repertory and could be compared with the family physician. The medical profession was far better organised than the dramatic. The part that could be played by the dramatist in the well-being of the nation was in every respect comparable with that played by the doctor—the mind was, of the two, more important than the body. The body was well guarded by the Government; there was a General Medical Council, a Ministry of

Health, medical officers of health, and poor-law hospitals, but at present nothing was done to protect the public's artistic life. She looked to the day when there would be a Ministry of Fine Arts and a national theatre, and when every town should have its dramatic building, belonging to the people and ensuring that the mind of the people should be safely guarded. It was impossible to over-emphasise the necessity for looking after this side of human life. Miss Ashwell spoke of her work in the war, and said that one experience was deeply engraved in the feelings of all her 600 helpers, that the great mass of the army liked the very best things; it was impossible to give them anything too good if it could be given well. The idea that the masses really preferred bad things was not true. They had found that the work of music and poetry and plays was definitely healing. Drama was the only way of bringing to people some vision of other people's lives. Immensely important questions that could not be broached on a political platform could be discussed through the medium of a play like "The Skin Game," where both sides were put in the form of struggling human feeling. Often that was the only opportunity the audience ever had of seeing both sides. Miss Ashwell related the story of a mutiny checked by the playing of "Candida," and of a fierce clerical opponent of the drama who found his healing from intractable war-obsessions, which church and hospital alike had failed to cure, in Barrie's "Dear Brutus." She begged doctors to think of this side of mankind that could only be fed by the arts, and to work for the day when the majority could have, at a price they could afford, the very best music, the very best plays, and the very finest kinema, instead of the constant reiteration of murder, of thieving, and of debased sex problems which were not the best thing for our older civilisation.

The Doctor in Shakespeare.

Sir STCLAIR THOMSON deplored the misunderstanding between sexes, classes, ages, and professions, and quoted Huxley's definition of heaven as "a place where I shall no longer be misunderstood." All classes, ages, and professions were very often misrepresented on the stage. Shakespeare had rather made fun of doctors up to King Lear, which was written in 1606, but in that play the doctor was a highly honourable and sympathetic character. In 1607 Shakespeare's daughter had married Dr. Hall, and it might be that the son-in-law had opened his father's eyes to the difference between properly qualified men and mountebanks, both inside and outside the profession. No surgeon appeared in a Shakespearean play, although Lear said "Let me have a surgeon; I am cut to the brains," and Portia warned Shylock: "Have by some surgeon, Shylock, on your charge, to stop his wounds lest he do bleed to death." Physicians appeared seven times in the 36 plays. In "Macbeth" there were two—an Englishman and a Scotsman. The former made a speech about the cure of scrofula by the royal touch:—

There are a crew of wretched souls
That stay his cure; their malady convinces
The great assay of art; but at his touch—
Such sanctity hath heaven given his hand—
They presently amend."

The Scots doctor was very canny. "I will set down what comes from her," he said, "to satisfy my remembrance the more strongly." And, "I think, but dare not speak," he said. It had been suggested that he was a timid man, trying to hand on a difficult patient to another practitioner: "more needs she the divine than the physician," regarding her as a criminal and declaring himself unable to minister to a mind diseased. There was no disparagement to the art and science of medicine in Shakespeare's distrust of physic; for to

"pluck from the memory a rooted sorrow, raze out the written troubles of the brain and with some sweet oblivious antidote cleanse the stuff'd bosom of that perilous stuff which weighs upon the heart."

What could be better than auto-suggestion, wherein "the patient must minister to himself"—a method of

recent recognition, but advocated by Shakespeare all those years ago. Macbeth, being a man of action, little given to reflection, called for his armour and his staff and threw "physic to the dogs." Another Shakespearean physician was Dr. Butts, in "Henry VIII." The original of this character was Dr. William Butt, Fellow of Gonville and Caius College, Cambridge, and of the College of Physicians, a man of great repute at court. Cornelius, in "Cymbeline," played a difficult part with great honour and astuteness when the queen asked him for poison. He reproved her with dignity, and when she insisted—and he could not disobey a royal command—he gave her a comparatively harmless drug, not trusting her statement that she required it for animal experimentation only. Doctors might ever lay this flattering unction to their souls that, nowhere in the whole of literature was found a nobler panegyric than the words of Cerimon in "Pericles":—

"I hold it ever,
Virtue and cunning were endowments greater
Than nobleness and riches; careless heirs
May the two latter darken and expend;
But immortality attends the former,
Making a man a god . . .
And I can speak of the disturbances
That nature works, and of her cures; which doth give me
A more content in course of true delight
Than to be thirsty after tottering honour,
Or tie my treasure up in silken bags,
To please the fool and death."

The Doctor on the Contemporary Stage.

Mr. IVOR BACK investigated first the dramatist's conception of life in Harley-street—for the dramatist, he said, the only street. Fruitless to protest to him that large fortunes had been accumulated in Brook-street or in Cavendish-square; he would not believe you. This street was long enough in real life—it had 145 houses—but on the stage it had nearly a thousand. In a recent play a surgeon had lived at No. 915. This immense and dreary avenue was peopled entirely by surgeon-baronets. In fact the surgeon-baronet was a comparatively rare bird, and many of them dragged out their miserable existence in the remotest recesses of provincial towns. To the dramatist the dweller in Harley-street was always a surgeon. Why? The reason was that the surgeon was the last of the great romantics. The soldier, the poet, the painter had had their day, but the surgeon was still to the public a queer romantic creature who spent most of his time doing operations of extraordinary gravity in which a slip of one-sixteenth of an inch to one side or the other meant the life of the patient. Admittedly it was difficult to introduce on the stage any complaint so hateful as the homely hæmorrhoid or so humdrum as the humble hammer-toe, but in real life the surgeon was called on to deal with these quite as often as with the graver abdominal lesions. Often the surgeon—although described as such in the programme—did not act like a surgeon at all, but indulged in the behaviouristic vagaries associated with the physician; he carried a stethoscope, he listened to chests, he talked, and he administered poisons. The stage surgeon nearly always had a large family of grown-up sons and daughters and led a kind of communal existence with them in one living room. If this room had a knee-hole desk with a stethoscope on it it was a consulting-room; if it had a grand piano it was a drawing-room. Whichever it was, it was peopled indiscriminately throughout the play by the surgeon, his family, his servants, and his patients. In one play Mr. Back had seen a patient examined in the presence of 11 other people, including one butler and one kitchen maid. If an operation was to be performed the stage surgeon, rang up a random number and ordered a nurse, without any question as to whether one were available or not. No one who had tried to get a surgical nurse at midnight for an emergency would need to be reminded of the real facts. On the stage the nurse arrived in a second or two, without cap, cloak, or luggage. In one play she had bounced on, turned on a gramophone, and danced a Charleston with the surgeon before making a single inquiry about the case. In another the operation had been performed in a

small room leading off the drawing-room, the audience being allowed to see a few towels and tin pans through the communicating door before the curtain mercifully fell. The great authors, other than dramatists, gave his due to the general practitioner, the devoted slave of the great British public and their guide, philosopher, and friend. He would add to the panegyric quoted by Sir StClair Thomson the words of Robert Louis Stevenson:—

"There are men and classes of men that stand above the common herd, the soldier, the sailor, and the shepherd not infrequently, the artist rarely, the clergyman more rarely still—the doctor almost as a rule. He is the flower, such as it is, of our civilisation, and when that stage of man is done with he will be thought to have shared as little as any in its defects. Generosity he has, such as is possible to those who practise an art, never to those who drive a trade; discretion tested by a hundred secrets; tact tried in a thousand embarrassments and, what are more important, herculean cheerfulness and courage, so that he brings air and cheer into the sick-room and often enough, though not so often as he wishes, he brings healing."

By the dramatist he was represented either as what the French called a "faux bonhomme"—a man full of beans, benevolence, and bunkum—or as a frank buffoon, or thirdly, as a venal scoundrel in the pay of the villain with a bottle of chloroform in his pocket. This he administered to his victims on a handkerchief, producing in two seconds a profound anæsthesia and complete muscular relaxation. The speaker wished that he would teach his technique to some of the surgeon's anæsthetist colleagues. There were innumerable examples of irresponsibility in nomenclature and technique, such as the "jugular artery" and operations on the head which in five minutes altered the patient's entire character. These errors might be avoided by invoking the assistance of a medical man. Sir Henry Irving, who had been very particular about accuracy, had once called on the two leading doctors of his time to assist him in a production. At the dress rehearsal these gentlemen were in the stalls, and a stage carpenter had been heard to murmur: "Sir Henry Irving, Sir H'Andrew Clark, Sir Frederick Treves—three blinking knights—and that's what the blinking play will run." Medical coöperation could not therefore be relied on to ensure success.

Mr. P. COLE remarked that the actor gave the public medicine just as the doctor did; but in a much more palatable form. The building in which the present meeting was being held had most interesting historical connexions with both professions.

Dr. CAMPBELL McCLEURE said he had never seen a stage doctor use the old-fashioned straight stethoscope with his ear at the right end. Another thing that had struck him was the ease of prescribing; the stage doctor dashed off a most complicated prescription in a few seconds, adding the words "two tablespoonsful in a draught of water three times a day after meals" with a single stroke of his pen. He pleaded for a little leniency and a little study on the part of great dramatists who presented medical men on the stage.

The President then called upon Dr. J. W. EYRE to propose, and Dr. T. B. HYSLOP to second, a vote of thanks to the speakers. The latter mentioned the difference between insanity as portrayed on the stage and as seen within the walls of Bethlem.

GREAT ORMOND-STREET HOSPITAL FOR SICK CHILDREN.—Mr. H. P. Macmillan, the chairman, and Lord Warrington of Clyffe, the vice-chairman of this hospital, have written to the press lamenting "the imminent failure" of the project for transferring it to the site of the Foundling Hospital. "The reason," they say, "is solely the want of money," the sum required being £600,000.

BECONTREE HOSPITAL.—It is proposed to erect a general hospital of 300 or 400 beds at Becontree, the new "dormitory" town by Ilford. King Edward's Fund have promised to contribute £10,000 towards the cost if voluntary contributions amounting to at least as much are forthcoming, and the Housing Committee of the London County Council (the owner of most of the houses) is recommending the Council to contribute a further £10,000.

Reviews and Notices of Books.

TOXINS AND TOXOIDS.

Handbuch der Biologischen Arbeitsmethoden: Abt. XIII., Teil 2, Heft 7. Edited by E. ABDERHALDEN.

Toxine und Toxoide. By E. LÖWENSTEIN, Vienna, Berlin and Vienna: Urban and Schwarzenberg, 1928. Pp. 109.

THE determination of the chemical constitution of toxin and of the chemistry of specificity are the main problems that allure and still baffle the immunologist. Obermayer and Pick, Landsteiner, Avery, and others have applied biochemical methods to the purification and separation of toxins, and this has led to the identification of the interesting haptenes, which react with antigens in vitro, but are not themselves antigenic when given alone; these workers and others have prepared the chemically altered specific antigens, diazo and nitrated protein antigens. Further interesting light on specificity comes from the racemisation work—though the author apparently does not mention it—of H. Dakin and H. W. Dudley. A difficulty in investigating the properties of toxins is that, like ferments, they seem to become more unstable the more they are "purified." Dr. Löwenstein confesses that we are not much nearer the solution of the problems connected with them than we were 30 years ago. The author deals mainly with typical toxins such as those of diphtheria and tetanus and their modification by physical and chemical means into toxoids, and with tuberculin. He deals at some length with the persistent quest of the immunologist to obtain a body which may be completely free of toxicity and yet will on injection give rise to protective antibodies. Ehrlich's unsuccessful attempts with iodine and Löwenstein and Eisler's work in Austria with iodine, and with formalin coupled with light or heat, from 1903 onward, are described at some length. These relate mainly to tetanus toxin. Ramon, in 1923, reinvestigated the process and, by formalinisation with heat, came nearer to success than any of the previous German workers in making a diphtheria toxoid and later a tetanus toxoid free of all toxicity but antigenic in character. Questions of priority are generally unattractive, but it is perhaps well that the history of formalinisation of toxin should have been put on record by Dr. Löwenstein. This record, together with the mention of the use of formalinised diphtheria toxin long prior to 1923 by A. T. Glenny and H. J. Sudmersen in this country, sets out the history of the investigation of the interesting and puzzling action of aldehydes—pre-eminently formaldehyde—on toxins. The chemistry of this action is still not clear.

Ramon's great contribution to immunology—the flocculation method—is well described. Dr. Löwenstein, after expressing his feeling that the French school did not carry out sufficient parallel researches on the determination of the binding value (or $L+$), does not share Ramon's conviction that the flocculation value of toxin or antitoxin is practically the only important measure of immunological value. He does not discuss the latest work, notably of Glenny in London and P. J. Moloney and colleagues in Toronto, which seems to suggest that though the flocculating value, $L+$, is at present the best ascertainable value of a toxin, it is not a complete expression of its immunising value, nor is the flocculation value always the true value of an antitoxin as measured in the classical Ehrlich method. The challenge to this latter method of measurement by R. Kraus and by Th. Madsen, who suggest that the "avidity" of an antitoxin is of more importance than the Ehrlich unitage, is mentioned. In the course of a discussion of various methods of active immunisation with toxin-antitoxin mixtures and toxoid, the author mentions that immunisation against diphtheria has been compulsory in schools in U.S.A. So far as we know this is

erroneous; any introduction of compulsion in connexion with this particular method of prophylaxis might well set back the clock.

Considerable attention is given to dissociation of toxin-antitoxin mixtures, and the author concludes this section with a rapid review of formalinised dysentery and gas-gangrene toxins, snake poison, abrin, and so forth. The final section describes the making and testing of tuberculin with a short description of the two components, the carbohydrate body of H. Zinsser and P. P. Laidlaw, reacting in vitro, and the purified tuberculin of F. Seibert and E. R. Long with its specific toxicity.

Though the bibliography is not as full as the specialist in this field would wish, this monograph is one which every immunologist will desire to have in his library.

THE PURDAH SYSTEM AND ITS EFFECT ON MOTHERHOOD.

Osteomalacia Caused by Absence of Light in India. By KATHLEEN OLGA VAUGHAN, M.B. Lond., sometime Superintendent of H.H. the Maharajah of Yammu and Kashmir's Diamond Jubilee Zenana Hospital, Srinagar, Kashmir, Cambridge, England: W. Hefter and Sons, Ltd. 1928. Pp. 48. 2s. 6d.

Miss Vaughan's little book is not a scientific treatise, but is an effort to show what an immense amount of unnecessary suffering the purdah system lays upon women in India. When purdah is strictly observed there is an almost complete lack of exposure of the skin to direct sunshine. Osteomalacia is very frequent, particularly among women of the child-bearing age, and Dr. Vaughan correlates its incidence with the lack of direct sunshine. The various claims of deficiency in light or in diet as the causal agent are discussed, and the author concludes that lack of light is the prime cause. If the osteomalacia described is really due to an avitaminosis with vitamin D, as it seems clear that it is, then it should certainly be curable by increased light; but it should also be curable by a better diet. One might put it that the light is insufficient when so poor a diet is consumed, or conversely that the diet is too poor when exposure to light is so deficient. It is unfortunate that so many writers still make an antithesis where none in reality exists. No doubt Dr. Vaughan is really tilting against the purdah system and would sooner see it abolished than insist on an alteration made in the dietetic habits of those who use it. From the point of view of prevention of osteomalacia the essential factor is the provision of vitamin D, and if this is easier to procure by advising alteration of dietetic habits than by urging the abolition of the purdah system, the more practical means of reform should be adopted.

THE CONQUEST OF LIFE.

By SERGE VORONOFF, M.D. Translated by G. GIBIER RAMBAUD, M.D. London: Brentano's Ltd. 1928. Pp. 201. 15s.

Dr. Serge Voronoff has written many works for the profession. He now turns his attention to the laity. His latest work is a popular exposition of the author's method of rejuvenation by means of grafts. It is, of course, natural that the public should desire to be kept informed of important advances in science, and there could be no advance of greater importance than one which claims to have the effect of postponing the ills of old age. It is doubtful, however, whether a book from the pen of an enthusiast concerning results which are still doubted by the majority of scientific men is to be welcomed. Interesting and important as are Dr. Voronoff's findings, they have not been accepted in their entirety by the medical world. The deputation of biologists and veterinary experts who recently visited the experimental farms in Algeria returned interested but unconvinced that Dr. Voronoff had proved his tenets. Many of his experiments lacked proper controls and no precautions.

had been taken to guard against unconscious selection. Moreover, although numerous cases have been recorded of improvement in health and increase of vigour following the implantation of testicular grafts in human beings, the results of these operations are by no means constant. His work, therefore, is yet in the experimental stage, and a popular exposition written in the vein of "The Conquest of Life" is somewhat premature. It will arouse various hopes in the minds of those who dread the arrival of old age. Life has not yet been conquered, and the hope that has ever been present in most hearts of finding the fountain of youth is still only a hope. Nevertheless Dr. Voronoff's book is stimulating. Some of his results cannot be put aside. The case of Jackie the Bull, who has twice been grafted and has now reached the age of 20 in apparent good condition, is sufficiently remarkable to make a sceptic pause and think. "The Conquest of Life" will not appeal to sceptics; but if, as the publishers' note puts it, it is meant to be "a narrative of surprising interest, as gripping as a best seller and as full of surprises as a mystery story," then the author has achieved his object.

THE GLORY OF DISCONTENT.

Studies in Modern Social Problems. By F. TUDSBERY. London: H. F. and G. Witherby. 1928. Pp. 232. 7s. 6d.

THE author of this little book is neither bolshevist nor cynic, but an amiable man who thinks that our relations with God and with one another might be much better than they are. He has written a series of pleasant simple essays to suggest that conventionality can be carried too far. These essays are not argumentative; the author tries always to see the third side of every question with a gentle reasonableness which many people will find helpful. It is a pity that he misquotes Wordsworth. The book would be welcome to many a convalescent.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXXI., Part 4. Pp. 597-930. October, 1928.—The Gram-negative Cocci of the Nasopharynx with a Description of *Neisseria pharyngis*, by G. S. Wilson and M. M. Smith (London). The classification and differentiation of these cocci are extremely muddled and unsatisfactory; several supposed species are united under a new name.—Tumours of the Skin and Mammary Glands caused by Pyrogenous Products of Cholesterol, by E. L. Kennaway and B. Sampson (London). "Tar" produced by heating cholesterol to about 800° C. is carcinogenic in mice (skin) and rabbits (mammary gland).—The Pathogenic Values of Pneumococcal Types: the Lesions Produced in Relation to Virulence, by J. F. Gaskell (Cambridge). The pathogenicity of Type II. and Type III. strains is lower than that of Type I. and the lesions produced are milder; Group IV. contains some strains which are highly virulent and pathogenic.—The in vitro Titration of *B. welchii* Antitoxin by its Antihemolytic Power, by J. H. Mason and A. T. Glenn (Beckenham). The method gives as good results as the direct toxin test in mice.—Histamine and Infection, by G. M. Findlay (London). Injections of histamine determine local infection by various bacteria and viruses; this is the explanation of the clinical association of trauma with, e.g., osteomyelitis and tuberculosis.—Polycythemia in the Rabbit Following Operations Involving the Peritoneum, by R. H. Mole (Moukden). A moderate degree of polycythemia follows four different operative procedures, under ether or novocaine anaesthesia, involving the peritoneum.—A Case of Endocarditis in Man Associated with *Bacillus parainfluenzae* of Rivers, by D. S. Russell and P. Fildes (London). A girl of 13 with a rheumatic history. The anatomy and bacteriology are fully described.—Giant-cell Tumours of Bone in a Fowl, by S. L. Baker (London). Two osteoclastomas:

transplantation failed.—Neuroblastoma of the Suprarenal Glands, by N. B. Capon (Liverpool). An example of the Pepper type of adrenal tumour with a review of the literature.—The Relation of Agglutination by Specific Serum to Agglutination by Acid, by J. A. Arkwright (London). In the typhoid group the flagellar and somatic agglutinable substances react with acid at different zones of hydrogen-ion concentration.—The Action of Immune Serum on Vaccinia and Virus III. in vitro, by C. H. Andrewes (London). Immune serum which is highly potent in preventing infection does not destroy vaccinia virus in vitro; there is no evidence of a stable antigen-antibody union, and a neutral mixture may be reactivated by simple dilution.—Capillary Permeability in Acute Uranium Nephritis, by the late Caroline Whitney (St. Louis). Uranium poisoning diminishes the permeability of the capillaries so quickly that it may be presumed to act directly and not through its nephritic effect.—Experiments on the Production of Hyperplasia in the Alveolar Epithelium of the Lung of the Rabbit, by J. S. Young (Leeds). Active proliferation of the epithelium of the marginal alveoli is caused by the intrapleural injection of sodium, calcium, strontium, and aluminium salts in proportion to their valencies.—The Appearance of Doubly Refracting Substances in Formalin-fixed Rabbit Tissues, by J. B. Duguid and J. Mills (Cardiff). Tissues which are apparently thoroughly fixed in formalin develop myelin substances on keeping in a slightly acid medium.—The Oxygen Tension Necessary for the Mitosis of Certain Embryonic and Neoplastic Cells, by G. P. Wright (London). In tissue cultures the lowest concentrations of oxygen at which cell division continues are for chicken heart myoblasts about 1.6 per cent., for Jensen rat sarcoma 0.8 per cent., and for a mouse carcinoma 0.4 per cent.—The Relationship Between the Bactericidal Power of Normal Guinea-pig Serum and Complement Activity, by J. Gordon and Arthur Wormald (Leeds). Hemolytic complement and bactericidal complement are probably identical; normal guinea-pig serum contains a bactericidal immune body.—Fixation of Complement by *B. typhosus* and Normal Guinea-pig Serum, by E. M. Dunlop (Glasgow). An interesting and useful study of natural antibody.—Chordoma of the Vertebral Column with Three New Cases, by D. F. Cappell (Glasgow). Two cervical and one dorsal case. The condition is related to the embryonic history of the notochord.—The Blood Changes After Splenectomy in Splenic Anæmia, Purpura Hemorrhagica, and Acholuric Jaundice, with special reference to Platelets and Coagulation, by W. Howel Evans (Liverpool). The platelets and blood coagulation time were studied before and after splenectomy in ruptured normal spleen (one case), splenic anæmia (five), purpura hemorrhagica (four), and acholuric jaundice (two). Except in one case of purpura there was a considerable rise of platelets and a diminution in coagulation time after splenectomy.—The Relation of the Blood Platelets to Thrombosis after Operation and Parturition, by R. Y. Dawbarn, F. Earlam, and W. Howel Evans (Liverpool). After many surgical operations and after childbirth the platelets in the blood begin to increase about the fourth day, reach a maximum about the tenth day, and then decline to normal. This is causally related to post-operative thrombosis.—The Types of Tubercle Bacilli in Human Bone and Joint Tuberculosis, by A. S. Griffith (Cambridge). In 598 cases bovine bacilli were found in persons of all ages in 20 per cent., in children under 5 in 33 per cent., in children between 5 and 10 in 24 per cent.; no case over 23 years yielded bovine bacilli. There is inconclusive evidence that bovine bacilli account for a relatively larger proportion of spinal cases.—*B. proteus* Infections, by J. F. Taylor (London). The organism is more pathogenic than is often supposed and is the active agent in a number of urinary and suppurative lesions.—A Sacral Neuroepithelial Tumour of Foetal Origin, by W. Susman (Manchester).—Obituary notices of W. H. Ferguson (portrait) and G. R. James.—Book received. Title page and indexes.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 10, 1928.

USE AND ABUSE OF COUGH.

How the secretions of the bronchial tree are brought up to the surface from the depths of the chest is the well-chosen subject of the Schorstein lecture which appears at the front of our present issue. In this lecture Dr. CECIL WALL deals in a learned and comprehensive manner with the facts and theories of respiratory movement, and in particular with the cough which is the final chapter in the physiological process of expectoration. Expectoration, he says, is effected by raising the intrapulmonary air pressure and then suddenly allowing the air to escape and carry with it any peccant matter that may be lying in the air passages, and he makes it clear how this mechanism can be put to the best advantage under various conditions. He does not deal in this lecture with the ciliary movement, described long ago by GOSSELIN, which is the first act of expectoration and was the subject recently of some very interesting experiments reported in our columns by Dr. LEONARD HILL (Oct. 20th, p. 802). SHARPEY showed that the direction of ciliary movement in the air passages of mammals and birds is towards the larynx. Dr. HILL does not state so definitely, but it may be assumed that the fact of ciliary movement and its direction holds good also in human beings. In an inquiry into the factors which govern ciliary movement he shows very clearly that the movements of the cilia can transfer, in a comparatively short time, secretion and foreign particles to the rima glottidis. The cilia act best in a neutral medium, their movements cease in acid or alkaline solutions, but begin again when sufficient alkali or acid is added to produce neutrality. The rate of transit when the trachea is horizontal is twice as fast as when it is vertical. Further, ciliary action is accelerated when the membrane is evenly stretched. Extensive damage to the membrane has the effect of stopping the movements of the cilia. Drugs applied locally vary in their effect. Solutions of ammonium chloride, absolute alcohol, oil of eucalyptus, caffeine, urethane, watery infusions of opium or belladonna apparently have no effect on the ciliary movement. Mercuric chloride, mercury alanin, carbolic acid, and arsenical war-gas fumes either slow the movement or abolish it altogether. Chloroform is more poisonous to the cilia than ether, but in the form of vapour as used for anaesthesia neither has any effect on ciliary movement. Dr. HILL does not himself suggest any clinical applications, but his observations, added to those of earlier investigators, make it certain that the ciliated cells of the tracheal and bronchial mucous membranes, by their powerful rhythmical movements, do transport bronchial and pulmonary secretion, mixed with foreign matter such as dust particles, up to the rima glottidis whence it is either swallowed or expelled as sputum. Ciliary movement is clearly the primary agent in the process of expectoration, to which the

muscular mechanism of respiration gives merely an approbatory fiat.

This factor of ciliary action is of more than academic interest. For if the conception of expectoration is restricted to the muscular mechanism of respiration, cough comes to be regarded as an explosive expiratory act depending on the presence of excessive secretion in the bronchial and alveolar trees. Whereas if the ciliary function is properly regarded, cough associated with sputum becomes for the most part an ill-controlled and unnecessary act, only really necessary when the cilia have been destroyed by inflammation or by trauma. Even in bronchiectasis, where large quantities of purulent sputum have to be expectorated, the act of coughing may be largely eliminated by making use of the force of gravity as in postural drainage. But the cough reflex is not necessarily associated with the presence of pulmonary secretion and subsequent expectoration. It is true that coughing may be initiated by irritation of the mucous membrane of the larger bronchi by such stimuli as irritating gases, cold air, and excessive secretion. In bronchiectasis coughing is only aroused when the contents of the cavities are brought into contact with the mucous membrane of the larger bronchi either by overflow or by a sudden change in position. With this exception the cough reflex originates, strange as it may seem, in the majority of cases in extra-pulmonary situations such as the larynx, the pharynx and nasopharynx, the mediastinal glands, the stomach, or the ear. To realise this one has only to recall the classical types of cough such as the stomach cough, the ear cough, and the throat cough, all types of reflex vagal stimulation; the pleuritic cough; the gander or brassy cough which is heard when the recurrent laryngeal nerve is involved in aortic aneurysm or in new growth of the mediastinal glands. Again the cough in pertussis bears a striking resemblance to that heard in children suffering from mediastinal enlargement. Clinical and radiological evidence alike suggest that the exciting cause of the cough is the same in both cases—namely, glandular enlargement producing reflex vagal irritation. Experience with lipiodol fails to disclose any cough reflex in the smaller bronchi and it seems that this chiefly comes into play when the secretion reaches the larger bronchi, the trachea, the larynx, and especially the pharyngeal wall. If the cilia are intact and their movement unimpaired, the act of coughing may be unnecessary and even harmful.

The best illustration of this thesis is to be found in a well-regulated sanatorium where the chorus of coughing is far less than that which greets the ear in railway carriages, restaurants, theatres, and churches. But relatively much more sputum is expectorated in sanatoriums than in public places. Patients who are taught to control their cough or to cough only at certain specified times soon become aware that sputum may be expectorated at the proper time with at the most a gentle "clearing of the throat," and that explosive coughing is not necessary. One of the important tasks which fall to the lot of the sanatorium physician is to teach the patients under his care to avoid useless coughing with its harmful increase in pulmonary movement and its grave risk of introducing infection into the sound lung. In other words, the physician has to teach the patient to recondition the cough reflex, and to allow the cilia to do the work which they are constructed to perform—i.e., to remove all harmful matter from the alveolar and bronchial tracts. The morning cough, prolonged to the point of vomiting, almost universal in patients suffering from pulmonary complaints and frequent in

inveterate smokers with no pulmonary lesion, is due to a collection of viscid mucus on the posterior pharyngeal wall. This tenacious secretion has been brought up overnight by ciliary action from the bronchial tree or has been excreted from the chronically inflamed mucous membrane of the pharynx. In either case the effect is the same—namely, to stimulate the cough reflex and sometimes the vomiting reflex. This cough can therefore best be relieved by a warm alkaline drink designed to render the mucus less viscid and to clear the pharyngeal wall. Dr. HILL's work itself suggests some clinical applications. If ciliary action is more rapid in the horizontal position than in the vertical the process of expectoration without cough should be accelerated by recumbency, provided, of course, that no other factors such as cardiac lesions preclude this posture. If ciliary action is accelerated by stretching the mucous membrane of the trachea and bronchi, extension of the head and neck might assist the expectatory process. In any case it would be worth while to test the effect of physical agents and drugs, locally applied or internally administered, on the rate of ciliary movement in the human bronchial tree.

THE FOUR PLAGUES OF EGYPT.

FEW persons not directly concerned realise the difficulty and importance of the Egyptian problem. It came to birth with the opening of the Suez Canal, when the growing Empire found an imperfectly organised population across its vital trade-route. It reached a baleful adolescence in the days of the Dual Control and the occupation, and at the time of GORDON's death it filled the English horizon. The genius of CROMER, MILNER, and KITCHENER kept it within bounds until 1914, but while the Empire was at war the Egyptian problem grew apace. The time for repressive measures had passed, and the remedy was tried of giving the country the utmost possible degree of autonomy. But against peace along these lines is the necessity of maintaining sufficient force in the background to protect the Canal and the European interests in Egypt if anarchy should command the situation. Politically the Nile Valley remains a flood that may burst its banks at any moment, and there are only flimsy barriers in the way of its disruptive power.

The peculiar bitterness of the Egyptian populace as a whole against Europe is due to the fact that while her Western neighbours have attained to a real civilisation, Egypt has never since the great days of the Pharaohs achieved more than a shadow. The apparent modernity of Egyptian institutions is a cloak held by various Western interests over one of the most ignorant and downtrodden peoples in the world. If the country were left to itself its railways, hotels, and most of its commerce would disappear in a few years. There are probably many reasons for this failure to become civilised, but none can be more important than that advanced by Dr. J. B. CHRISTOPHERSON in his presidential address delivered on Nov. 1st to the Section of Tropical Diseases and Parasitology of the Royal Society of Medicine. It is impossible to have a sound mind in an unsound body, and Egypt is physically rotten. The foreigners and educated classes together, says Dr. CHRISTOPHERSON, do not number more than half a million, and the vitalising element of the country is the fellahin, the agricultural population of 14 millions. This huge class is practically illiterate, is ground down in the mud of its cultivations by tyranny great and

small, and is ravaged by the four plagues of bilharzia, hookworm, pellagra, and ophthalmia. Dr. CHRISTOPHERSON might have added to this list diabetes and sexual perversion, both of which are widespread. Bilharzia and hookworm are traceable directly to the river and the soil from which the race springs; pellagra is presumably a food-deficiency disease, and the ophthalmic infections are spread by flies which breed in the dirt of the villages. Probably 75 per cent. of the nation suffer from bilharzia, and the four plagues together account, in Dr. CHRISTOPHERSON's opinion, for one-third of all the deaths. These afflictions impose on their hosts a hopeless mental and moral handicap; they undermine self-confidence and manhood and make their victim ineducable and uncivilisable. The proof of this is in the incredible change that comes over the fellah who is cured of them. Dr. CHRISTOPHERSON describes the ordinary untreated peasant as a man of good physique with a somewhat hang-dog expression, a pale, sallow, muddy complexion, not over-clean or tidy, cruel, unreliable, impulsive, fanatical, and easily influenced to criminal acts. He has no ambition, and his habits are those of 2000 or 10,000 years ago. The "nafr" in the Egyptian Army, who is nowadays kept free from his endemic diseases, is a fine worker, capable of steadiness and devotion, possessed of a very keen sense of humour and an original talent for impromptu acting. The Church Missionary Society recognise that no amount of educative effort is of any use until these diseases are eradicated, and at their hospital in Old Cairo 13,167 persons were cured during 1926 and 1927. The possibilities of a hookworm campaign are reviewed on p. 992 of our present issue.

Dr. CHRISTOPHERSON's conclusion, that Egypt's need is not so much for law or for the material benefits of civilisation, as for physicians to cure her four plagues, will be endorsed by everyone with practical experience of the country. They are for her the root of all evil. If the fellah had a healthy body he would be educable; if he were educated he could be civilised and politically enfranchised as nowadays, whatever the appearance of things may be, he certainly is not. If he were civilised he could be left in charge of his own country without the constant suspicious supervision that seems indispensable to-day and is so irksome and humiliating to those Egyptians who wish to fulfil their obligations to the West. Truly, he who will cure the four plagues may have of Egypt anything he wishes.

POST-OPERATIVE THROMBOSIS.

Post-operative thrombosis is at best a nuisance and at worst a serious and dangerous sequel to surgical operations and childbirth. Its underlying cause or causes and the precise mechanism by which it is produced have never been satisfactorily explained; all that has been fairly certain is that it is more likely to occur in older than in younger people and after extensive rather than slight operations, and especially in those involving the abdomen. Behind all the statistics of its incidence is the difficulty that small clots may occur without any symptoms at all and as, once started, a thrombus propagates itself, its size and destiny are to some extent accidental; hence the occurrence of white legs or pulmonary emboli may not be a very satisfactory guide to the conditions underlying post-operative thrombosis in general. Recent work¹ in Prof. E. E. GLYNN's laboratory in Liverpool, begun by Dr. W. HOWEL EVANS and

¹ Jour. Path., Bact., 1928, xxxi., 833.

carried on with Dr. F. EARLAM and Dr. R. Y. DAWBARN, seems to throw a good deal of light on its immediate mechanism and holds out some prospect that its basal cause may be soon discovered and something done to prevent it. That blood platelets have an intimate relation with clotting has been shown in a variety of ways; W. CRAMER, for example, found that filtered plasma would not clot, L. ASCHOFF and others have observed that an accumulation of platelets was anatomically the basis from which an intravital thrombus grows, and J. TAIT has recently pointed out that threads of fibrin may actually be seen to form along the tracks of particles emanating from platelets. The Liverpool workers show from the examination of a number of normal and diseased persons that clotting time, as measured outside the body, varies inversely with the number of platelets counted in the circulating blood; diminution of platelets is even more plainly associated with failure of the clot to retract. Frequent counts on 50 surgical cases revealed the new fact that after operations the number of platelets in the blood begins to rise about the fourth day, increases to a maximum about the tenth day, and thereafter falls slowly back to the normal level. It can hardly be a coincidence that clinical thrombosis and embolism most frequently appear about the tenth day after operation. The extent of the rise varies widely; in one case it was absent and in a good many quite small. In the greatest increase the platelets were two and a half times as abundant as they were before operation; on the average they increased by about 50 per cent. Analysis of the individual cases shows that the more substantial rises occurred after the larger operations, but apart from this, no connexion with any particular operation is obvious, nor does the age of the patient seem to be important. Much the same was found in 28 cases of childbirth; six showed no significant platelet rise, but the average increase was to 240 per cent. of the prelabour level and the largest to 470 per cent. The combination of operation and delivery in five cases of Cæsarean section gave even more marked increases. Control observations show that the platelets are not influenced by stopping in bed, by anaesthesia, or by simple hæmorrhage; with sepsis they may either fall or rise. These items of surgical operations being excluded, it is not a little suggestive to find that platelets also increase after fractures and during convalescence from lobar pneumonia. The feature which is common to these various circumstances is tissue injury, and if the suggestion that the absorption of breakdown products is the immediate stimulus is correct it remains to discover how it influences the platelets; possibly the normal activity of the spleen in destroying them is depressed. This interesting work includes at present no practical directions for avoiding post-operative thrombosis, though examination of the blood about the sixth day might show in which patients it was likely to develop, any count of 750,000 or thereby being a sign of danger. Lytic sera or some other agent which destroys platelets suggest themselves as possible remedies, but they might be dangerous, for platelets are particularly effective in promoting clotting when they disintegrate. Again, some means of stimulating the spleen to greater activity may be found, and it may be that the preventive effect which some surgeons attach to bodily exercises may be due as much to promoting the splenic circulation as to quickening the general blood flow. However, the matter will doubtless receive the further investigation which it deserves and the Liverpool observations certainly indicate a line along which prevention may be hopefully looked for.

Annotations.

"Ne quid nimis."

THE LORD MAYOR'S SHOW.

THE programme of the Civic Procession which is to pass through the streets of London to-day, Friday, contains welcome evidence of the growth of public interest in health and social welfare. Industry as represented by the City Guilds has long been a prominent feature of the Lord Mayor's Show, but the wider aspects of public hygiene have never before been presented on this scale. The National Milk Publicity Council is sending a car, drawn by a team of four Suffolk Punches, representing milk as a health promoter. An immense milk bottle in an appropriate setting is surrounded by children dressed to represent the food fairies in the milk. Two cars are arranged and shown by the Industrial Welfare Society, which encourages the study of questions affecting the welfare of workers engaged in industry, and assists and advises employers on starting and improving schemes for the welfare of their employees. The Health and Cleanliness Council in its exhibit contrasts the clean and the dirty home. Finally, the King Edward's Hospital Fund for London is represented by a car illustrating the progress made in the cure of disease and in the care and treatment of the sick, culminating in our great voluntary hospitals as we see them to-day. A mediæval apothecary is first shown at work in his laboratory. There follows a section of an up-to-date children's ward, with a child undergoing sunlight treatment. London is beginning to take its health conscience seriously.

LATE RESULTS OF OPERATIONS FOR GASTRO-DUODENAL ULCERATION.

At this year's congress of the Association Française de Chirurgie there was a brisk discussion¹ on the late results of surgical treatment of ulcers of the stomach and duodenum, and it is interesting to compare the opinions there expressed with those held by authorities in this country. In reviewing his experience of so-called radical resection methods and indirect methods, which include gastro-enterostomy, gastro-duodenostomy, and enervation of the stomach, Mr. J. Okinczye pointed out that from time to time we must reconsider whether a peptic ulcer is to be regarded as a local condition or as the expression of a general disease. Is it logical to speak of gastric resection as radical treatment? He believes that surgery can only claim to palliate the local manifestations of the disease, and that no operation at present executed can be selected either for its intention or its results to the exclusion of all others. Most of them seem to be rewarded with a certain measure of success, and the conditions of failure are veiled in obscurity. Possibly the results depend in some way upon the state of evolution of the disease at the time of intervention; symptoms seem to follow a cycle, and operations towards the end of this cycle might well prove more successful than at other times. Too little, however, is known of the factors influencing the course of the disease to enable us to choose the most propitious moment for surgery, and Okinczye's conclusion is that the most important indication for operating is the failure of relief from medical treatment pursued for a reasonable time. The seat of predilection for ulcer, he suggests, seems to be the pyloric antrum, but sometimes a functional disturbance of this area pushes the disease (as it were) into the duodenum, or, after gastro-jejunostomy, perhaps into the jejunum. Should this view be accepted duodenal ulcer must be looked on in the light of a complication of a trouble which has its centre primarily in the stomach. If so, it is

¹ See *Presse Méd.*, Oct., 1928.

rational to attack the stomach in seeking to cure the duodenal lesion, and in fact Okinczye reports 78 per cent. of good late results from resection operations compared with 66 per cent. for gastro-jejunostomy. A mortality of 13.6 per cent., however, was associated with the former. At the same meeting Mr. X. Delore, of Lyons, declared that gastro-jejunostomy is a very satisfactory method of treatment for duodenal ulcer, giving 70 to 80 per cent. of good late results. But gastro-duodenectomy, he considers, is followed by a higher percentage of permanent cures. In 62 cases of duodenal ulcer 28 gastro-duodenectomies (45 per cent.) were performed with one death, whilst gastro-jejunostomy was performed in the rest. Thus, while he regards gastro-duodenectomy as the method of choice there remains a large field for gastro-jejunostomy, the results of which are improved if the duodenal ulcer is excised or cauterised locally. On all these questions there is little unanimity, as is illustrated by the interesting experience of Prof. Henri Hartmann.² Surgeons in this country are almost all agreed that for an ulcer of the lesser curvature gastro-jejunostomy is not very suitable, yet Prof. Hartmann is strongly in favour of such an operation, when it is of the posterior type and the anastomotic opening abuts on the greater curvature of the antrum. The mortality, he says, is about one half that of gastric resection, and this very largely compensates for the fact that resection gives better immediate results.

PIRATE SURGEONS.

ON Nov. 7th, before the Historical Section of the Royal Society of Medicine, an address on Pirate Surgeons was given by Dr. Philip Gosse, who is well known as the greatest, or possibly only, living authority on the exciting topic of piracy. He opened his remarks by explaining that the title chosen had apparently caused some misapprehension in certain quarters, and he earnestly reassured his hearers that he had no intention of mentioning the names of any living persons. His remarks were concerned with the medical men who, in the seventeenth and eighteenth centuries, sailed with the buccaneers and pirates to stitch up their wounds and trim their beards. He included the buccaneers, although these were not, strictly speaking, pirates, but the distinction was often so slight that it seemed unnecessary to differentiate between them. Actually the buccaneer who was British, French, or Dutch, practised his adventurous craft in the Spanish-American seas, and preyed upon Spaniards only. The pirate proper, on the contrary, took a wider view of his profession, and in his own words "waged war upon the whole world," irrespective of nation or kinship. One of the chief of the pirate surgeons was Captain Thomas Dover, an amazing character who remains immortalised by the diaphoretic powder attributed to him; he sailed the seas, if not as a pirate captain, as a very open-minded privateer, and was the author of a medical "best-seller" entitled "*The Ancient Physician's Legacy to His Country*," in which he claimed that almost every ill to which the human body was subject could be cured by copious draughts of metallic mercury. He also sacked Guayaquil in Peru, cured 172 sailors of plague, and rescued Alexander Selkirk: and yet, in spite of all this, so distinguished a Member of the Royal College of Physicians failed to achieve the honour of becoming a Fellow. Amongst the less well-known surgeons was Lionel Wafer, who also wrote a book, describing his hardships and adventures crossing the Isthmus of Panama in 1681 with some other mutinous buccaneers. Wafer got left behind in the jungle and was captured by a none-too-friendly chief, but owing to his skill in bleeding one of the chief's wives he became the inseparable companion of the delighted potentate. Alexander Exquemeling, the Flemish barber-surgeon, was the author of a remarkable work, "*The History of the Buccaneers of America*," 1684, which gives a lucid but accurate

account of the doings of those extraordinary "brothers of the coast." Dr. Gosse then spoke of some of the lesser lights, such as Dr. Bullock, who took part in the plundering of a Spanish-American town, but becoming drunk, was left behind in the retreat to the ships, to be captured and afterwards to become a popular practitioner of medicine and "civilly entertained especially by the women" in the same town. Then there was Richard Jobson, who tired of the dull routine of a druggist's assistant in London, and ran away to sea to become a buccaneer, which he combined with the study of divinity, carrying always with him "a Greek testament which he frequently read and would translate extempore into English to such of the company as were disposed to hear him." A less lovable pirate was Dr. Peter Scudamore, surgeon to Captain Bartholomew Roberts, of the *Royal Fortune*. He did many things unbecoming to one of his learned profession, as stealing the surgical instruments belonging to a brother surgeon, and, what gave even greater offence, a backgammon board from a fellow pirate. He could talk the Angolan tongue, and was caught red-handed attempting to foment a mutiny amongst a hold-full of stolen slaves. At last the gallows claimed him, when he died penitent but unregretted, at a wholesale hanging of pirates at Cape Coast Castle in 1722.

As the lecturer pointed out, the glimpses of the adventures of the surgeon aboard a pirate vessel were all too brief, and it was only occasionally that the veil was lifted for a moment to show us something of the lives of these obscure practitioners of surgery.

BORNA DISEASE.

AT a time when a great deal of attention is being paid to acute infections of the central nervous system in man, more than usual interest attaches to the publication by the Medical Research Council of a special report¹ on a form of encephalomyelitis in sheep and cattle, which goes by the name of Borna disease. The condition is fortunately still unknown in the British Isles, so that the studies here presented have no immediate application in this country; but every addition to our knowledge of the viruses which attack the nervous system and of the changes to which they give rise in the brain and spinal cord is valuable at present.

The investigations here described were made by Mr. S. Nicolau and Mr. I. A. Galloway, working as guests at the National Institute of Medical Research at Hampstead. The disease concerned has been known, under several names, for more than a century as an enzootic and epizootic affection of horses, cattle, and sheep, and during the last few years various workers have shown that it is attributable to a filter-passing virus, and that pathologically its most distinctive feature is the presence in the ganglion cells of the hippocampal gyrus of certain "inclusions," referred to as Joest-Degen bodies. The transmission of the disease under natural conditions is probably by the respiratory tract or by ingestion. From the experiments now recorded and from earlier work it appears that the virus of Borna disease has properties common to the viruses of vaccinia, herpes, rabies, and poliomyelitis—the "neurotropic ectodermoses" of Levaditi. Under favourable conditions it passes through bacteria-proof filters, and through collodion ultra-filters which permit the passage of colloidal particles of large dimensions; after centrifugalisation for 15 minutes at 5400 revolutions per minute the supernatant fluid remains infective; it is resistant to the action of glycerine, but is sensitive to desiccation, ultra-violet light and heat, and is destroyed by ether, chloroform, and formalin, and it has not been propagated in vitro. Rabbits can be infected experimentally with the virus by intracerebral or intrathecal

¹ Borna Disease and Enzootic Encephalomyelitis of Sheep and Cattle. By S. Nicolau, D.Sc., and I. A. Galloway, B.Sc. M.R.C.V.S., Medical Research Council, Special Report Series No. 121. London: H.M. Stationery Office, 1928. Pp. 90. 5s.

² Chirurgie de l'Estomac. Paris: Masson et Cie. 1928.

inoculation, by inoculation into a peripheral nerve (sciatic), or into the anterior chamber of the eye, and also—in animals whose brain or meninges have been irritated by normal saline or serum—by application of virulent material to the scarified skin. The presence of the virus in the brain, spinal cord, peripheral nerves, parotid, and adrenal glands of rabbits dead of the disease has been demonstrated by the injection of portions of these organs into the brains of other rabbits. Monkeys have been inoculated intracerebrally and have developed encephalomyelitis after a very long incubation period (33–71 days); and in one animal the symptoms resembled those of poliomyelitis. Pathologically Borna disease resembles poliomyelitis, herpes encephalitis, and human epidemic encephalitis in the infiltrative character of the lesions. In the experimental rabbits perivascular and parenchymatous infiltration by mononuclear cells was found throughout the central nervous system, and there was also an interstitial infiltration in the peripheral nerves and very intense inflammatory changes in the dorsal root ganglia. Satellitism and neuronophagia of the ganglion cells were widespread if not very intense. In the monkey the findings were similar, but the incidence was less upon the spinal cord; the characteristic intracellular Joest-Degen bodies were found in many parts of the brain. A solid immunity against Borna disease can occasionally be obtained in the rabbit by inoculating suitably attenuated virus into the brain, and immunity has also been produced by multiple intravenous injections, by corneal scarification, and by intratesticular inoculation with fresh virulent material.

The viruses which attack the central nervous system may be divided into two groups according to the type of pathological change to which they give rise. On the one hand, there are those which excite considerable infiltrative interstitial reaction, such as the viruses of poliomyelitis, encephalitis lethargica, herpes, and rabies; on the other, there are those which cause perivascular demyelination with little infiltrative reaction, the best known being that associated with vaccination. The virus of Borna disease is now placed in the former group, and this work of Nicolau and Galloway has widened our knowledge of the group as a whole. One fact which they have proved is that when virus is inoculated into the brain it may spread not only throughout the central nervous system but also into the peripheral nerves; this is probably a general rule for viruses of this group. These same workers have shown that it is true in the rabbit for the viruses of rabies and herpes, and in man it is known that poliomyelitis may give rise to infiltrative lesions in the peripheral nerves and dorsal root ganglia, though the actual presence of infective material in these situations has not, to our knowledge, been demonstrated. In the particular case of Borna disease the virus, spreading peripherally, strikes severely at the posterior root ganglia, and there is an argument by analogy that herpes in man may also be a central infection spreading peripherally and producing its most intense effects on the posterior root ganglia, the central parts of the nervous system having greater powers of defence against it.

THE SEMON LECTURE.

THE evolution of laryngo-rhinology has followed a course which might have been predicted. On looking backwards it is easy to realise the errors into which it has fallen and the dangers to which it has been exposed, and as all special branches of medicine are in their infancy exposed to similar dangers, the progress of this one may serve as a guide and an example to younger specialities. After sporadic and uncertain attempts by various pioneers extending over a century, Manuel Garcia in 1854 was the first to obtain a satisfactory view of the interior of the larynx and, by presenting a paper on the subject to the Royal Society of London, became the founder of laryngology. Czermak, of Pesth, and Türck, of Vienna, developed the method, and the latter city became, and has

ever since remained, a great centre for the study and teaching of the allied sciences of laryngology and rhinology. Last week Prof. Markusz Hajek, of Vienna, came to London to deliver the Semon lecture and received an enthusiastic welcome from his old pupils and from his numerous friends and admirers in this country. He took as the subject of his lecture Laryngo-Rhinology and General Medicine, and he pointed out, with a wealth of illustration drawn from his long experience, the pitfalls which have beset the path of his specialty. At first the new discovery was followed by a rapid improvement in technique and by the invention of numerous instruments of examination and treatment, and the result was a tendency for laryngology and rhinology to become divorced from general medicine. An instance of this was the indiscriminate local treatment of tuberculous laryngitis which followed in some quarters the pioneer work of Heryng and Krause in this field. This phase has now happily passed, and all laryngologists agree that the most important part of the treatment is that of the general affection, and that local treatment of tuberculous laryngitis should only be carried out in close coöperation with the physician. The danger now, he thinks, comes rather from the opposite direction, and is that clinical diagnosis may be pushed into the background by laboratory methods. There is a tendency to rely too greatly on all kinds of examinations, histological, bacteriological, and serological, and a consequent danger that the clinical acumen of the experienced practitioner may not be given the full scope formerly accorded to it. These laboratory methods are of great value and importance, but they also are subject to fallacy, and the clinician should be guided but not ruled by them.

GAS ATTACK ON RATS.

RAT week is a suitable time to refer to recent work on the use of cyanogen compounds for destroying these troublesome rodents. An investigation¹ has been made at the New York Quarantine Station by Surgeons C. V. Akin and G. C. Sherrard, in order to determine the relative efficiency of these products from the standpoints of (1) lethal efficiency, (2) safety to fumigators and to others, and (3) cost. Cyanogen compounds are dangerous things to handle, and not long ago the Prefect of the Seine forbade² the use of hydrocyanic acid for the destruction of vermin in houses, where the use of selective poisons or of virus is the method of choice. But ships are not houses, and they are in many ways specially adapted for treatment by fumigation. Moreover, the destruction of rats in ships is even more important than in houses, since rats entering ships from plague-infested ports may introduce this disease into other ports.

The New York investigators studied the action of liquid hydrocyanic acid (about 98 per cent. HCN), both alone and containing 20 per cent. of cyanogen chloride (tear gas) added to serve as an indicator, to the fumigator or other humans entering the treated space, of the presence of residual traces of gas. They also worked with the gas generated from sodium cyanide in situ by the addition of mineral acid, also using a mixture of sodium cyanide and chlorate to yield, when acidified with hydrochloric acid, hydrocyanic acid with a small proportion of tear gas. Further they tried a German preparation, Zyklon-B, of hydrocyanic acid adsorbed on "diatomite"—a silicious material similar to keiselguhr—and made pungent by the addition of chloropicrin, as well as a preparation of calcium cyanide containing free hydrocyanic acid (CaCy₂, 2HCN), which yields its hydrocyanic acid on exposure to moist air and carbonic acid. The solid products are sold in air-tight cans or pails, and as they, especially the calcium cyanide, are finely divided, care must be exercised in

¹ Public Health Reports, vol. xliii., No. 41, Oct. 12th, 1928. Comparative Efficiency of Cyanogen Products used in Fumigation.

² See THE LANCET, 1928, i., 1340.

distribution so that the residual material left after fumigation can all be removed from the ship's hold or other compartment. Spreading in thin layers on paper is recommended. It was found that rats, which were all of one breed, varied considerably in their resistance to the poison, and no opinion could be offered as to the relative susceptibility of these rats and wild rats. They were usually placed in cages at both floor and ceiling level in the test-rooms in which a standard dosage of 2 oz. of HCN per 1000 cubic feet was used as a rule. Diffusion of the gas was found to be slow, which, having regard to the small difference between its density and that of air, is not surprising. Also, as the gas is slightly lighter than air, the rats at ceiling level succumbed sooner than those on the floor. The authors say: "It is a well-known fact that rats escape cyanide fumigation as fumigation is usually done, and the reason for this becomes clear when it is seen that a lethal quantity of the gas will not flow through small openings into tightly closed sections not primarily exposed to the gas. The practical proof of this was witnessed on shipboard when test animals, concealed in the covered bilges, closed drawers, and similarly tight compartments, were unaffected by standard amounts of cyanide during the course of a two-hour fumigation." The importance of careful preparation of a ship before fumigation is therefore obvious.

Experiments showed that the residues of the solid preparations, more especially from calcium cyanide, should be removed with great care to avoid danger. A concentration of one-tenth of an ounce of hydrocyanic acid in 1000 cubic feet of air, in the opinion of the authors, "must be considered as dangerous to human beings exposed over a long period of time, and they also suggest that rats which are well enough protected in living quarters to escape a dose of 1 oz. of HCN per 1000 cubic feet will also survive a two-hour exposure to the standard dose." The lethal efficiency of liquid acid is much greater than that of gas generated from cyanide *in situ* and still more so than that of calcium cyanide. Zyklon-B is very effective—obviously it is in effect liquid acid. The conclusion was forced on the authors that less than the theoretical amount of gas was evolved into the air from sodium cyanide by the agency of mineral acids. A wise note of warning is struck in respect of the absorption of hydrocyanic acid by bedding, mats, rugs, &c., which are not dry and which are best removed before operations commence. Conversely the protective effect of layers of damp sacking or similar materials on rats hiding under them should be considered, as it is very great. "If managed with due care and proper respect," the investigation concludes, "hydrocyanic acid is the best of all fumigants for rodents. Careless use of it will be attended with human fatalities, but it will kill rats under conditions that the use of sulphur cannot meet; and it is obvious that if fumigation does not kill rats, time and money are wasted." Incidentally, it kills those minor horrors of life at sea—cockroaches, bugs, and the like. At well-equipped fumigating stations with a highly-trained personnel liquid acid will be found the best agent to use. For smaller ones Zyklon-B has advantage. The liquid acid is not a very safe substance to convey on account of some tendency to undergo violent decomposition, and should not be sent by common carrier. The lessons learned in the course of the experimental work covered in this report point insistently to one conclusion: *Fumigate fewer ships better.*

DAWSON WILLIAMS MEMORIAL PRIZE.

At the general meeting of subscribers to the Dawson Williams Memorial Fund, held on July 10th last under the chairmanship of Sir Humphry Rolleston, it was resolved that the sum subscribed to this memorial should be devoted to a prize in pædiatrics, to be awarded every two years or at longer intervals, and that the scope of the prize and the details of its adjudication should be left to the discretion of the trustees, with the assistance of such other persons as they might wish to consult. The following have

agreed to act *ex officio* as trustees: the Presidents (for the time being) of the Royal College of Physicians of London, the Royal College of Surgeons of England, the British Medical Association, the Royal Society of Medicine, the Section for the Study of Disease in Children (R.S.M.), and the Editor of the *British Medical Journal*. The Medical Secretary of the British Medical Association acts as convener and secretary of the trusteeship, and the first meeting of the trustees was held at the House of the Association on Oct. 19th, with Sir John Rose Bradford, P.R.C.P., in the chair. It was decided to ask the Charity Commissioners to accept for investment the sum of £849 now in hand, to receive all interest accruing therefrom, and to pay this over to the trust account at the bank for the purposes of the Fund. In pursuance of the resolutions of the meeting on July 10th it was resolved that the Dawson Williams Memorial Prize should take the form of an award for the best work done in pædiatrics during the five years immediately preceding the date of the award; that any registered medical practitioner in the British Empire should be eligible for the award; and that the first award, to be made by the trustees in July, 1930, should consist of a cheque for 50 guineas.

PAY BEDS IN LONDON HOSPITALS.

FIVE years ago¹ we published a list of 13 general hospitals in London which provided accommodation for patients of moderate means. It contained the names of three hospitals with medical schools attached, providing between them 108 pay beds, and ten other hospitals, mostly general, with resident medical officers, providing between them 213 pay beds. In the report of the special committee on pay beds of King Edward's Hospital Fund for London, published in July, 1928, the first of these two groups contained the names of six hospitals, providing 164 beds, and the second the names of 22 hospitals, providing 358 beds. It is true that the area surveyed by the special committee was much wider than that covered by our own inquiries, which made no claim to be exhaustive, but even so the increase that has taken place in hospital accommodation for paying patients during the last five years is significant. It has a bearing on a doubt, expressed by the special committee referred to above, as to whether the nature and extent of the existing pay-bed accommodation at voluntary hospitals is generally known by members of the middle and professional classes. The committee suggested that King Edward's Hospital Fund might well consider the wisdom of preparing and publishing year by year, for the information of the public, a list of the pay beds at the London voluntary hospitals, with rates of charge and other particulars. We are informed that the management committee of the Fund are at present considering this recommendation and would be glad to know whether a list such as is included in the appendix of the report of the special committee, if prepared and issued annually, would be likely to be of use to the public and the medical profession throughout the country. It seems to us clear that it is of the utmost importance for practitioners to be kept up to date with developments of this kind, and we would urge the Fund to proceed with arrangements for the annual issue of such a list. The appendix to the report includes also particulars of 22 general, cottage, and other hospitals without resident medical officers who admit paying patients, 8 hospitals for women, and 24 other special hospitals. As further evidence of the importance of an annual supplement to the information here provided is the information that of the teaching hospitals not hitherto providing pay beds the Middlesex, St. Bartholomew's and St. Mary's have schemes for establishing such beds, while St. Thomas's, the Royal Free, King's College, and Westminster Hospitals propose to add considerably to the number of private wards at present available. Many other extensions of this sort to general and special hospitals are contemplated, and

¹ THE LANCET, 1923, II, 1000.

it seems certain that an annual list will be not only of great practical use but will be a valuable index of the trend of hospital administration in London.

A GREAT PHARMACIST.

PHARMACY has suffered a heavy loss by the death in his sixty-third year of Mr. Edmund White, which occurred at his home at Putney on Nov. 3rd. It is no exaggeration to say that Mr. White was the greatest pharmacist of his day and generation. There have been pharmacists with a wider range of scientific knowledge than he possessed and pharmacists with a larger place in the sphere of business, but it is doubtful if there has been in our time another pharmacist in whom the learning of the schools and the wisdom of the market-place were so happily blended. Possessing this valuable combination he gave his services to the craft in which he was reared, although he must have been tempted at times to utilise his qualities in fields where the prizes are more plentiful and the work less exacting. To-day it is by no means uncommon for a pharmacist to graduate in science at one of the universities, but in the days when White took the degree of Bachelor of Science it was an unusual if not a novel achievement for one of his calling. Before that, he had obtained during his apprenticeship days the Bell Scholarship which entitled him to a free course of instruction in the Society's School of Pharmacy, an institution which has been foster-mother to many men who have since gained distinction in other vocations. At the completion of his courses he obtained the Pereira medal, the most coveted prize offered to pharmaceutical students, and after that he stayed for a time at the school working as a demonstrator. From there he went to St. Thomas's Hospital as chief pharmacist, where he remained for a long period, acting at the same time as one of the Pharmaceutical Society's examiners. He was elected a member of the Council some years before the outbreak of war and held the office of President during the war years. His services to his country during that exacting period were of great value; his position as head of a venerable organisation equipped with resources for research work and even, at a crisis, for carrying out manufacturing processes enabled him to throw himself and the Society with him into the work of producing some of the drugs and chemical reagents, for our supplies of which we had until then depended upon continental sources. Those who were associated with him in those days will recall the eagerness with which he set to work on this important task. Too old for service in the field, he fought the good fight in the arena for which he was so admirably accoutred. We are told that on the very day war was declared he spoke with his colleagues very strongly of the desirability of voiding enemy patents, and although we cannot go so far as to say that it was he who suggested the policy eventually adopted by the Government in this matter, it is clear that he was one of its earliest advocates. The importance of Mr. White's life work vis-à-vis the medical profession lay in his constant advocacy of higher and higher education for pharmacists. He was of the school which believes that pharmacy is the handmaid of medicine and that the true rôle of the pharmacist is to study the science of drugs. It was his view, and he persisted in it in the teeth of the most obstinate opposition from the commercial school, that the pharmacist's proper function could not be performed unless he had a good educational foundation, and unless on that ground-work there was erected a specialised structure of a much more enduring nature than that which passed muster a few years ago. He succeeded in convincing his colleagues to that end, and the pharmaceutical student to-day will find it very difficult to obtain registration as a pharmacist unless he works hard and systematically. The day of "cramming" for the qualifying examination has gone; for this the thanks of the medical profession are due to Edmund White more than to any other man. A closing word should be said concerning his views on the production of

the British Pharmacopœia; he held that if the pharmacist was more highly educated he should be more highly esteemed both by the medical profession and the public. That is to say, he stood out, to use a colloquialism, for due recognition for the pharmacist whether he was in his shop or helping to revise the Pharmacopœia. As a corollary, if pharmacists through their Society gave valuable assistance to the General Medical Council in the work of producing the Pharmacopœia, that work should be recognised in a more conspicuous way than had been customary in the past. Edmund White was the Pharmaceutical Society's representative on the Commission for the Production of the British Pharmacopœia, and no better one could have been chosen.

GENERAL MEDICAL COUNCIL ELECTION.

THE result of the voting for two Direct Representatives for England to be members of the General Council of Medical Education and Registration in the place of the late Dr. J. A. Macdonald and of Sir Robert Bolam, who has been appointed to represent the University of Durham, is as follows:—

Ernest Kaye Le Fleming, M.R.C.S. . .	11,455
John Wardle Bone, M.B. . .	11,340
Gordon Reginald Ward, M.R.C.S. . .	4,262
Edward Andrew Gregg, L.R.C.P. . .	3,108

The constituency numbered 32,758 (as compared with 29,179 at the 1924 election), of whom 15,082 (last time 15,229) took part. The proportion of those taking no part was thus rather more than one-half of the possible voters, suggesting that interest in the election was notably less than four years ago. The number of invalid votes received was 720. Only 368 voting papers, or 1·12 per cent. of the whole number, were returned as dead letters. An effort will be made by the Registrar of the Council to get into touch with all practitioners whose papers have been returned in this way before their names are erased from the Register under Section 14 of the Medical Act, 1858.

The next session of the Council will commence at 2 P.M. on Nov. 27th, when the President, Sir Donald MacAlister, will take the chair and give an address.

Sir Wilfred Grenfell, F.R.C.S., of Labrador, has been elected Lord Rector of the University of St. Andrews.

THE Secretary of State for Scotland has appointed Dr. John Parlane Kinloch, medical officer of health of Aberdeen and head of the Public Health Department of Aberdeen University, to be Chief Medical Officer in the Department of Health for Scotland which on Jan. 1st will take over the powers and duties of the Scottish Board of Health.

THE Council of the British Institute of Radiology incorporated with the Röntgen Society has decided to hold a special meeting at the opening of the new session on lines similar to the meeting last year, when the new body was inaugurated. The date has been fixed for Thursday and Friday, Nov. 15th and 16th, and besides the presidential address by Mr. G. W. C. Kaye, D.Sc., papers have been promised by Prof. W. L. Bragg, F.R.S., Sir Thomas Horder, Mr. W. Sampson Handley, Mr. A. J. Walton, Mr. G. Shearer, D.Sc., and others whose work is connected with radiology. Most of the meetings will be held at the Central Hall, Westminster, and there will be an exhibition of X ray and allied apparatus which is said to include exhibits by all the British firms engaged in this industry. The proceedings will not be open to the general public, but anyone who is practically interested in radiological work is invited to attend. The Director of the Institute, Dr. J. Muir, 32, Welbeck-street, London, W. 1, will be pleased to give any information desired. The Mackenzie Davidson Memorial Lecture will be delivered by Prof. Bragg, at 8.15 on Nov. 14th, at the house of the Royal Society of Medicine, 1, Wimpole-street, W. The subject is X Ray Optics.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

X.—THE INTERPRETATION OF THE BLOOD COUNT.

By S. C. DYKE, D.M. OXF., M.R.C.P. LOND.,
CONSULTING PATHOLOGIST TO THE WOLVERHAMPTON AND
STAFFORDSHIRE HOSPITAL.

PART II.*—THE WHITE CELLS.

IN this country the term leucocyte is usually regarded as embracing all the varieties of white cells; in America there is a tendency to confine the use of the term to polymorphonuclear cells. To avoid confusion it is safer to use the term "white cells" to cover all classes, reserving the term leucocyte for special application.

THE WHITE CELL COUNT.

Knowledge of the total number of white cells per c.mm. of the blood is of the utmost importance in the diagnosis of a number of conditions, but it is of very little use unless the relative percentages of the various classes of cells is also known. The total and differential counts will therefore be considered together.

There is no fixed normal figure for the total number of white cell in the circulating blood. Their numbers are subject to physiological variations depending upon exercise, upon the stage of digestion, and even fluctuate throughout the day without apparent reference to any particular cause. Variations of 1000 or more per c.mm. in the same patient on different days need then excite no surprise. The following table must therefore be regarded only as a rough guide to the limits of variation in the normal person.

White Cells of a Normal Person.

Total No.	5500 to 8500 per c.mm.
Polymorphs	Neutrophile .. 60 to 75 per cent.
	Eosinophile .. 0 to 2 per cent.
	Basophile .. 0 to 1 per cent.
	Lymphocytes 25 to 40 per cent.
Mononuclear	Monocytes .. 2 to 7 per cent.

In normal healthy adults the white count will usually be found to lie somewhere between 5500 and 8500 per c.mm. Figures above or below these, however, need not be regarded as necessarily abnormal. A decrease is spoken of as a *leucopenia*, an increase as a *leucocytosis* or *lymphocytosis* according to the type of cell involved. Before going into the question of variations in the total numbers it is necessary to consider the types of cells.

Types of White Cells.

Normally five classes of white cells are found in the blood. These fall into two divisions, those with lobed nuclei and those without. The first are spoken of as polymorphonuclear, the latter as mononuclear cells.

In the *polymorphonuclear* order, the cells, according to the nature of the granules in the cytoplasm, are again divided into *neutrophile*, *eosinophile*, and *basophiles*. Of these three classes the neutrophiles are by far the most common, forming from 60 to 75 per cent. of all the white cells. Eosinophiles and basophiles may be so scanty as not to be found in an ordinary examination; the former are seldom present to an extent of more than 2 and the latter of more than 0.5 per cent.

The most important and plentiful of the *mononuclear* order are the *lymphocytes*; the remaining

order of this class is constituted by that type of cell variously known as the endothelial, large mononuclear, or transitional cell, and also by many other names. The name *monocyte* is coming into general use for this cell, and it is to be hoped that in course of time it will replace all others. Lymphocytes are further divided by those who like doing this sort of thing into large and small, but the distinction appears to be without importance. Lymphocytes normally occur as from about 25 to 40 per cent. of the white cells; the monocytes seldom exceed 7 per cent.

Embryonic Forms.—Certain other cells of types usually confined to the bone-marrow or elsewhere in the hæmatopoietic system may also occur in the blood stream under abnormal circumstances. The most important of these are the embryonic forms of the cells ordinarily occurring in the blood. The young forms of the polymorphonuclear order of cells are known as *myelocytes* and *myeloblasts*. In these cells the nucleus has not yet acquired its adult lobed condition, but is mononuclear. Myelocytes show granules in their cytoplasm and can thus be divided into the same three classes as the polymorphonuclear cells; myeloblasts, being younger and less differentiated, have not yet acquired the cytoplasmic granulation.

The embryonic forms of the lymphocytes are known as *prolymphocytes* or *lymphoidocytes*. They have unlobed nuclei and clear cytoplasm, and are thus very difficult of differentiation from large lymphocytes or even from myelocytes. Finally, megakaryocytes normally only present in the bone-marrow, may occasionally appear in the blood stream.

Changes in Number and Proportion of White Cells.

In the interpretation of the white count by far the most important points for consideration are the total number of white cells, their relative proportions, and the presence or absence of embryonic forms. It is impossible to dissociate the consideration of these three factors from each other.

Roughly speaking, it may be said that the lymphocytes are much less liable to numerical fluctuations than the polymorphs. As the factors governing variation in the monocytes are little understood, it therefore follows that in the consideration of the differential count the relative proportions of the polymorph and mononuclear orders of cells is of prime importance.

Leucopenia.—A decrease in the total white count (*leucopenia*) is always associated with a decrease of the polymorphs. The mononuclear cells usually remain at about their normal level, but on account of the decrease of polymorphs are relatively increased. Such a diminution of the polymorphs with relative increase of the lymphocytes is characteristic of conditions in which the activity of the bone-marrow is depressed and may reach a high degree in aplastic anæmia; it is a characteristic feature of Banti's disease and may be present to some degree also in primary anæmia. The leucopenia of typhoid fever is an early and constant diagnostic sign; it may be present also in measles, influenza, and tuberculosis, but less constantly, and therefore of correspondingly less diagnostic value.

Leucocytosis.—An increase in the total number of white cells usually depends upon an increase in the polymorphs, but there are exceptions to this rule. Where the white cells are increased over 10,000 per c.mm., and where the polymorphs make up over 80 per cent. of the total, the condition may properly be spoken of as a leucocytosis. When, however, the lymphocytes are increased so as to make up 40 per cent. or more of the white cells, the state of affairs is usually referred to as a lymphocytosis.

Leucocytosis is characteristic of infections due to the "pyogenic cocci," and to all infections associated with the production of pus, except renal tuberculosis. Within certain limits the degree of leucocytosis is proportional to the severity of the infection and to

* Part I. on the Red Cells appeared last week.

the capacity for response on the part of the patient; thus, in pneumonia, a high degree of leucocytosis is a hopeful prognostic sign. A white count of 40,000 per c.mm. indicates a very vigorous response; figures above this up to even 100,000 per c.mm. or over are met with from time to time but are rare.

A leucocytosis, together with pyrexia, practically always indicates the presence of a "septic" condition. The one important exception is lymphadenoma or Hodgkin's disease; the aetiology of this condition is unknown, and it is possible that actually it is an infective condition; in any case it is not infrequently associated with a considerable leucocytosis and a high but irregular temperature. In the absence of physical signs pointing to some such infective condition as pneumonia or meningitis, the presence of a leucocytosis serves as an indication for a thorough and unremitting search for some area of local inflammation or pus formation. The presence of a leucocytosis with some degree of pyrexia may serve to point to the presence of active septic inflammation in cases not doing well after operation. A rising leucocyte count, with marked increase in the percentage of polymorphs, should rouse suspicion of the presence of pus.

Although a leucocytosis is usually indicative of the activity of an infection, it is important to remember that it may occur in certain toxic states and also as the result of the action of some poisons. Of the former, cirrhosis and acute yellow atrophy of the liver are the commonest examples; of the latter, carbon monoxide and the salicylates, colchicine and quinine in large doses are those most likely to be met with in practice. Certain substances, such as nucleic acid and cinnamate of sodium are, of course, injected parenterally for the purpose of producing a leucocytosis; in the presence of an acute infection they are not usually successful in so doing, nor is there any reliable evidence that such leucocytosis as may be produced in this way has any therapeutic value.

Hæmorrhage may produce a moderate degree of leucocytosis; after a single hæmorrhage this disappears in three or four days, but if the hæmorrhages persist the leucocytosis will persist likewise.

Lymphocytosis, as explained above, may be absolute or relative. Absolute lymphocytosis—that is, an actual increase in the total number of lymphocytes—is rare, except in the case of lymphatic leukaemia, which will be referred to later. It occurs in whooping-cough and in small-pox, but the best example is afforded by that rare condition, glandular fever or acute infective mononucleosis. In this condition the white count may rise to 30,000 or 40,000 cells per c.mm., of which 80 to 90 per cent. may be lymphocytes; in the face of such a blood-picture the differential diagnosis from lymphatic leukaemia may be difficult; a valuable diagnostic point is that this latter condition is always associated with a high degree of anaemia, while in glandular fever anaemia is usually absent or only slight. Relative lymphocytosis is always associated with a leucopenia and has already been referred to.

Variations in the percentages of the classes of white cells normally found in the blood other than the neutrophile polymorphs and lymphocytes may sometimes give assistance in confirming a diagnosis, but their importance is usually not great.

Eosinophilia, or an increase in the percentage of the eosinophile polymorphs, is associated with many protozoal infestations. Perhaps the commonest of these is echinococcal or hydatid infection. The presence of an eosinophilia may assist in confirming a diagnosis of this condition, but its absence must never be taken as negating it; the same applies to trichiniasis, filariasis, and to the presence of intestinal worms. The increase of the eosinophiles in true spasmodic asthma may sometimes help to confirm the diagnosis where the history is poorly given and no attack has been observed. Eosinophilia is the rule in pemphigus and dermatitis herpetiformis, but does not usually greatly assist the diagnosis. An

eosinophilia, together with a neutrophile leucocytosis, occurs in a good many cases of lymphadenoma, but this condition has no constant blood-picture and can only be certainly diagnosed by the examination of an excised gland.

Basophilia, or an increase of the basophile polymorphs, is rare and has no diagnostic significance.

The *monocytes* are said to be increased in chronic malaria. Inasmuch as one pathologist's monocyte or transitional cell may be another's large lymphocyte little importance should be attached to variations in the percentage of these cells.

Megakaryocytes properly belong in the bone-marrow and only appear in the blood when it is subjected to great stress of activity. They may figure in the blood-films in primary anaemia and in cases of pneumonia with a high degree of leucocytosis. Their appearance has no diagnostic or prognostic significance. Under similar circumstances of red marrow activity, and particularly in children, occasional embryonic forms of the white cells may also appear in the blood stream. Their presence in large numbers, however, is indicative of an entirely unrestrained and abnormal activity on the part of the hæmatopoietic system, and on it depends the diagnosis of leukaemia.

The Leukæmias.—There are two types of leukaemia dependent upon the involvement of those portions of the hæmatopoietic system concerned respectively with the formation of cells of the polymorphonuclear and of the lymphocytic order. In the former cases the condition is spoken of as myeloid, myelogenous, or medullary; in the latter as lymphatic leukaemia. Mixed types have been described, but it is highly improbable that they ever occur; a lymphoidocytic leukaemia is also sometimes described, but it is probable that all such cases are examples either of a lymphatic or of a myeloid leukaemia, in which the majority of the cells are myeloblasts.

In the vast majority of cases of leukaemia one or other of the classes of white cells will be found to be enormously increased, the percentage of the other class being relatively diminished, but the numbers remaining actually normal. Thus the total white cell count in a case of myeloid leukaemia may be 100,000, of which the polymorphonuclears, myelocytes, and myeloblasts may make up 98 per cent., leaving only 2 per cent. of lymphocytes. In spite of this great relative diminution the actual number of the lymphocytes remains normal at about 2000 per c.mm.

In describing the blood-picture in a case of myeloid leukaemia the pathologist will usually specify the percentages of the different types of normal and embryonic cells present. In some cases, where the majority of the embryonic cells are of the myeloblastic type, the pathologist may be in doubt as to whether he is dealing with myeloblasts or prolymphocytes. The cytoplasm of the former cells contains granules demonstrable by special peroxidase stains, and to be sure with which type he is dealing, the pathologist may feel obliged to apply one of these stains. The presence of oxidase granules in the cytoplasm definitely classes the cells as myeloblasts and places the leukaemia in the myeloid category. Failure to apply this technique probably accounts for some of the anomalous cases showing the apparent blood-picture of lymphatic with the clinical signs of myeloid leukaemia.

It is important to bear in mind that a mere increase in the number of the white cells does not entail a diagnosis of leukaemia. As pointed out above, in a simple leucocytosis the cells may occasionally attain 100,000 per c.mm., and cases of 200,000 per c.mm. have been reported. Nor does the presence of an occasional embryonic form justify this diagnosis. To establish the diagnosis, embryonic cells must be present in considerable numbers; this is almost more important than the presence of a high total count, for cases of leukaemia with only a moderate increase of the white cells have been recorded.

There is a tendency to think that the more embryonic the type of cell present the more virulent

and deadly must be the leukæmic condition. On the assumption that large lymphocytes are younger than small ones, some hæmatologists regard the occurrence of cells of large size in lymphatic leukæmia and the preponderance of myeloblasts in myeloid leukæmia as indicating the likelihood of any early fatal termination. Clinical findings do not appear to support this view.

MEDICINE AND THE LAW.

Cross-examination under Anæsthetic.

Lord Lee's Royal Commission would be startled by the procedure at a police investigation in Hawaii last September, when a suspected person, who had steadfastly protested his innocence, was injected with hyoscine by a police surgeon in the endeavour to elicit information from him while under the influence of the drug. The case was one of murder. An American school-boy was abducted from his school on some pretext by a man somewhat vaguely described as an "oriental." According to reports in the local newspapers which have just reached this country, the boy's father received a letter demanding a ransom of 10,000 dollars for his son; he attended at the appointed place and paid the money. The police, although they had apparently been notified, failed to appear at the meeting; later the body of the murdered boy was found in some bushes. Suspicion fell on a 20-year-old Japanese who had been chauffeur in the boy's family. The chauffeur, whose name was Kaisan, was arrested and was examined by what in England would probably be labelled "third degree" methods. He steadily maintained his innocence and his ignorance of the murder even though he was pressed with questions by expert examiners, one of whom, according to the newspaper report, "has obtained more confessions from criminals than any other man in Honolulu." Among the test imposed upon him was a direction to copy the original letter in which the ransom was demanded. As the English law-courts well know, the conclusions of a handwriting expert are occasionally fallacious. Two experts, however, were apparently satisfied that Kaisan's handwriting was identical with that of the original letter. Of the two experts—one a bank clerk, the other Dr. Stanley D. Porteus, professor of psychology in the University of Hawaii—the latter seems subsequently to have changed his mind; thus at this stage little had been done to connect Kaisan with the crime, and, in the words of the newspaper report, "Kaisan, after being quizzed constantly for 12 hours, was returned to a cell and again questioned there by Deputy City Attorney Brooks without result." In this dilemma, we are told, the police surgeon administered "a heavy injection of hyoscine hydrobromide" to Kaisan. "The drug produces a twilight sleep from which persons emerge to talk from their subconscious mind and to reveal truths that they had secreted during full consciousness. Under the effects of this drug Kaisan confessed to the writing of the ransom letter, describing in detail the process." But when the effect of the drug wore off, Kaisan repudiated any confession and steadily asserted his innocence. A few hours later a second injection was administered with entirely negative results. At this stage the real murderer was discovered elsewhere, confessed to the crime, and was dealt with; it thus became unnecessary to exhaust the resources of medicine in the attempt to extract a confession from Kaisan.

Six years ago Dr. E. House, of Ferris, Texas, read a paper¹ before the State Medical Association of Texas on the Use of Scopolamine in Criminology. Experience obtained in obstetrical practice might, he suggested, be turned to account in the detection of crime. He was

even able to describe two tests made upon alleged criminals. In both cases, he said, his subjects, while under the influence of the drug, gave answers which, when corroborated, proved their innocence. The drug, by depressing the power of reasoning or imagination, elicited nothing but truthful answers. Why, asked Dr. House, should this method not be available in criminology? The bloodhound's trail may lead to the suspect's door, but corroborative evidence is indispensable before conviction; similarly, all data secured by the use of scopolamine would equally require corroboration.

In this country the answer would be that we have evolved a procedure under which statements made by accused persons to the police are not normally admissible in evidence unless the accused person has first been cautioned in a formula of words adopted on the advice of experienced judges. We cannot therefore accept a method which would negative that caution and which would trick a suspect and catch him off his guard. It would be instinctively repulsive alike to judge, counsel, and jury, apart even from the fact that English courts of law are conservatively distrustful of scientific discovery in its application to criminal investigation. To dope a man into confession would be as distasteful as to extract evidence by torture.

Successful Defence of Post-epileptic Automatism.

In a murder trial at Lancaster Assizes on Oct. 30th evidence was given by mental specialists which suggested that the accused had killed his wife while in a condition of post-epileptic automatism. The evidence indicated that the man armed himself with a revolver and cartridges and sought out his wife, who was living apart from him. He fired three shots at her and as she was being taken helpless into a neighbour's house he fired a fourth shot into her back at point blank range. He was then disarmed by the driver and conductor of a passing motor-omnibus, to whom he remarked "I have done it this time." He was asked to go to the police station, but declined, and said he would wait for the police. Later he said to a constable: "There is nothing to be afraid of; I have done it, and am ready to take my punishment; the only thing I am sorry about is my little daughter." The evidence of witnesses was that his manner was calm and deliberate and that he appeared to know perfectly well what he was doing. The accused in the witness-box gave various details of his history. As a young man he had been struck on the left ear with the prong of a hay-fork while haymaking. He had wandered away from home from time to time and had not known where he had been. He joined the army in 1897, had Mediterranean fever at Gibraltar, and malaria and sunstroke in India. He rejoined in the Great War, was blown up by a shell, suffered from shell-shock, and was eventually discharged. Major O. D. Jarvis, R.A.M.C., gave evidence of the finding of a medical board in 1922 that the accused was suffering from petit mal; there was, he said, a condition of post-epileptic automatism in which a man might do things about which he seemed quite able to reason, though entirely unconscious of what he had done. Asked by Mr. Justice Humphreys if he knew of an instance of automatism occurring after an attack of minor, as distinguished from major, epilepsy, Major Jarvis replied that he could not recall an actual case at the moment, but that from his reading he was satisfied that automatism might occur even after minor epilepsy. In answer to a further question from the judge, the witness said the accused might make statements to the police in a state of automatism, though, if he afterwards made a statement referring to acts done in the automatic state, the fact would be against the theory of automatism. Dr. Alastair Robertson Grant, deputy medical superintendent at the Whittingham Mental Hospital, who had interviewed the accused and had seen his army medical history sheets, said that automatism was frequently associated with petit mal. Dr. Arthur Lowndes, of Longton, also gave evidence. The jury found that the accused was "guilty of the act charged but insane at the

¹ See THE LANCET, 1922, II., 1082, 1190.

time." The case is interesting in that the learned judge, who has had special experience of the administration of the criminal law, put the defence of post-epileptic automatism to the jury in more sympathetic terms than are sometimes used in our courts.

New Dangerous Drugs Regulations.

The Home Office announces its intention to make fresh regulations under the Dangerous Drugs Act for the purpose of consolidating into one code the seven different sets of outstanding regulations, a proposal of great convenience which all will approve. It is also proposed to apply the existing provisions to certain drugs and preparations recently brought within Part III. of the Act of 1920—namely, extract and tincture of Indian hemp, dihydro-oxycodone, dihydrocodeinone, and preparations containing them, and preparations containing less than one-tenth per cent. of diacetylmorphine. An announcement regarding these was noted lately when the 1925 Act was brought into force. It is further proposed that the new regulations shall provide for constituting a tribunal to which cases may be referred when there is reason to think that a dentist may be contravening the Dangerous Drugs Regulations. The constitution of such a tribunal for medical practitioners was one of the recommendations of the Departmental Committee on Morphine and Heroin Addiction. It was a valued concession of self-government to the medical profession and a wise recognition of the existence of adequate alternatives to proceedings in the police-court; its extension to the profession of dentistry will be an indication that the system has been found satisfactory.

INTERNATIONAL CONFERENCE ON HEAT AND LIGHT IN MEDICINE, SURGERY, AND PUBLIC HEALTH.

THE congress was addressed on the second¹ day of the proceedings by Dr. C. B. Heald, who read a paper on the development of new electrotherapeutic apparatus. Dr. Heald spoke of apparatus now in use at the Royal Free Hospital, among other appliances mentioned being a new rhythmic myotrope and a tunnel for infra-red light baths. Dr. F. Nagelschmidt spoke on foam-treatment, a new method of applying external heat. By adding a small quantity of non-toxic non-absorbable saponin solution to water of any desired temperature and blowing a current of air through the mixture a fine foam is produced. The foam contains little moisture and is very stable. The patient is laid in a bath containing a few inches of water of the desired temperature. Saponin solution is added, air blown through, and the patient is covered with the foam. Local treatments also can be given. Dr. Nagelschmidt described another application of foam treatment; oxygen is blown through the solution and a fine foam is produced which is less stable than air-foam. It has remarkable cleansing properties when brought into contact with mucous membranes and is very suitable for vaginal and urethral irrigations, intranasal treatment, and so forth. Saponin, although not itself absorbed, is said to facilitate the absorption of other substances, and is a suitable medium for dissolving drugs for local medications.

Dr. C. Conyers Morrell contributed a paper on plant pigments in relation to photosensitisation, embodying much of his original work in this field. The importance of sensitisation by plant pigments, its common occurrence, and the part played by it in animal metabolism is now recognised, and Dr. Morrell's paper will encourage further work in this direction.

On the third day of the conference Dr. F. Talbot read a paper on actinotherapy and dental caries.

¹ A report of the proceedings on the first day appeared in the annotation columns last week (p. 934).

Dr. Talbot considers vitamin D to play a part in the arrest as well as in the prevention of dental caries. The part it plays in the development of healthy teeth is already established. Comparing the teeth of the children in a home, one year after the installation of a carbon-arc lamp, with their teeth in the three years previous to irradiation, he observed distinct improvement; there was less caries, arrest of caries in some cases, and healthier gums. He considers that general treatment, not local irradiation, is of value, and that probably irradiation is of greater value than cod-liver oil in these cases.

Dr. A. J. Cemach, of Vienna, spoke on ultra-violet therapy in oto-rhino-laryngology. Dr. Cemach treats lupus of the larynx by direct irradiation with the quartz mercury-vapour lamp. He introduces a small water-cooled burner into the mouth and guides it with the finger past the epiglottis. Constitutional treatment, tuberculin, and general light treatment in suitable cases are given concurrently. In early cases a cure may be expected, in more advanced ones sometimes a cure and always relief of pain. Extensive lung involvement is not considered by him to be a contra-indication to this method of treatment.

Sir Henry Gauvain showed cinematograph films of life at Alton and Hayling, which illustrated the part played by heliotherapy in the treatment of surgical tuberculosis. Films illustrating artificial light treatment were also shown. Sir Henry Gauvain stressed the fact that light treatment is only one of the factors in the treatment of surgical tuberculosis and should never be regarded as the only factor.

Dr. M. Weinbren spoke on ultra-violet radiation in the treatment of chronic pulmonary tuberculosis. He agreed with Rollier that cachexia and toxæmia are the main contra-indications to radiation in phthisis, and to the treatment of any other condition by light. He did not find it necessary to adhere to Rollier's method of exposure, but gave full baths with suberythema doses from the start. He found that in some cases, even among out-patients, there was evidence of improvement as shown by weight, X ray appearance, and general condition, and deduced that light treatment given cautiously to selected cases could prove of value even when it was given under the worst possible conditions for success—to hospital out-patients.

On the last day of the conference Dr. Albert Eidinow read a paper on photosensitisation. Sensitisation with eosine previous to light treatment gave deeper reactions and increased desquamation. Intravenous injections had now been abandoned in favour of local injections (into the lesion) in the treatment of lupus. Painting the skin with eosin was useless and merely cut off the light before it penetrated to the living cells.

Mr. T. C. Angus read a paper on the efficiency of ultra-violet light apparatus, with regard to the emission of light of given wave-length and current consumption. Dr. L. Hill, who presided, referred to the importance of the phenomenon of photosensitisation, which permitted the longer and more deeply penetrating rays of the spectrum to be used. He could not accept statements which had recently been made that rays of short wave-lengths penetrated much deeper into the skin than had previously been estimated. A paper by an American investigator, Dr. M. J. Dorcas, of Cleveland, U.S.A., on energy distribution of various types of arc lamps was read in the author's absence, and his slides showing energy curves were demonstrated.

The Lessons of the Congress.

It was apparent from the contributions to the congress that the principles on which actinotherapy is based are beginning to emerge as an exact science, but that its application and limitations in treatment are far from being yet clearly defined. There can no longer be any doubt that actinotherapy will occupy a definite and probably an important place in therapeutics, but there is much need of further critical investigation. Even on such fundamental questions as the extent of the range of physiologically

active rays there is little information and no agreement. The advantages of whole-body over localised irradiation, apart from cases in which irradiation is used to produce intense inflammatory reactions, must depend to some extent on the size of the area irradiated and on the amount of skin which must normally be irradiated to obtain a minimum or optimum general effect. On this point also we have only very scanty information. There is still no accepted unit of dosage. While the physiological action of the various regions of the spectrum is still so little known it would be unwise to attempt to express dosage by a physical formula, and with the apparatus at present in use it would be impracticable to attempt treatment using a narrow portion of the spectrum only. But it is clear that until the dosage is defined no fair comparison of results obtained by different observers can be made.

The Exhibition.

At the Medical Exhibition held in connexion with the conference, the leading firms manufacturing ultra-violet light apparatus were represented. Comparing this year's with last year's exhibits, it was noteworthy that the prices of apparatus were on the whole considerably lower, and also that the smaller and less luxurious types of stand were favoured. There were not many new models, but some of the burners have been improved, and elimination of the heating coil in the atmospheric type of burner (K.B.B.) is an improvement. A stand with improved vertical and horizontal movement is exhibited by the Medical Supply Association. High-frequency electrodes (Gallois), exhibited by Messrs. Kelvin, Bottomley and Baird, are said to combine ultra-violet radiation, capable of producing erythema with high-frequency treatment. Vita-glass Manufacturing Board exhibited samples of Vita-glass showing improved glazing and greater transparency.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THE BUCKSTON BROWNE TRUST.

THE dinner at the Royal College of Surgeons on Nov. 1st was the first of a series of feasts made possible by the generosity of Mr. G. Buckston Browne, F.R.C.S., who gave a sum of £5000, the interest from which should afford an annual opportunity for social intercourse between Fellows and Members of the College. By the terms of the trust at least half of the invited guests must be Members of the College, and in the following account Members are indicated by an asterisk (*).

The guests were received in the Hall of the College by the President, Sir Berkeley Moynihan, and the Vice-Presidents, Prof. Hey Groves and Mr. Warren Low, and dinner was served in the Library, the quality of the menu being indicated by the fact that Messrs. Ring and Brymer were the providers. On the right of the President sat Lord Dawson of Penn,* Sir George Newman, Sir Anthony Bowlby, Major Leonard Darwin (sole surviving son of Charles Darwin), Sir William Bragg (Director of the Royal Institution), Sir Richard Luce, M.P., Mr. C. H. Fagge (c), Dr. E. Collingwood Andrews,* Mr. R. P. Rowlands (c), Dr. Graham Little,* M.P., Sir Edward Pollock (the next-to-Senior Fellow), Mr. W. Sampson Handley (c), and Dr. Astley V. Clarke* (Leicester). On the left of the President sat Sir Thomas Barlow,* Sir Alfred Hopkinson, K.C., Sir Thomas Holland (Rector of the Imperial College of Science), Sir John Rose Bradford,* P.R.C.P., Lieut.-Colonel F. E. Fremantle, M.P., Sir Alfred Rice-Oxley,* Mr. F. J. Steward (c), Dr. Charles Edwards* (Andover), Lieut.-Colonel C. T. Samman,* Sir William Lister, Dr. A. Owen Lankester,* and Dr. Arthur H. Bostock* (Chichester). In addition to these there were also present other Members (c) of the Council of the

College as follow: Sir Holburt Waring, Sir Cuthbert Wallace, Mr. J. Herbert Fisher, Prof. G. E. Gask, Mr. W. McAdam Eccles, Sir Charles Gordon-Watson, Mr. Victor Bonney, Mr. Hugh Lett, Mr. Leonard P. Gamgee, and Mr. R. G. Hogarth, and the following Fellows and Members: Sir Arthur Keith (Conservator), Mr. G. Buckston Browne, Mr. C. A. Griffiths (Cardiff), Mr. J. A. Hayward, Mr. H. W. Armstead, Sir John H. Parsons, Mr. J. F. Dobson (Leeds), Mr. W. H. B. Brook (Lincoln), Mr. T. H. Openshaw, Mr. Thomas H. Bickerton (Liverpool), Mr. Henry Colgate (Eastbourne), Mr. Raymond Johnson, Sir George Thane, Mr. Macleod Yearsley, Mr. J. F. Jennings, Mr. E. F. White (Crowthorpe), Dr. T. Wilson Parry,* Dr. H. Bellamy Gardner,* Dr. G. de Bec Turtle,* Dr. E. Le F. Payne* (Kew), Dr. Guy Wood* (Charterhouse), Dr. Rickard W. Lloyd,* Dr. E. M. Callender,* Dr. Frank Savery,* Dr. L. Haden Guest,* Dr. Ernest Ware,* Dr. Maurice Newfield,* Dr. P. Sidney Spokes,* Dr. George Parker* (Bristol), Dr. E. G. Moon* (Broadstairs), Dr. H. B. Brackenbury* (Chairman of Council, B.M.A.), Dr. Alan Randle,* Dr. T. W. Shore,* Prof. H. E. Roaf,* Prof. C. Lovatt Evans,* Dr. G. A. Buckmaster* (Bristol), Dr. C. W. Hutt,* Dr. P. H. Manson-Bahr,* Dr. W. H. W. Atlee* (Eton), Dr. J. O. Symes* (Clifton), Dr. Walter Broadbent* (Brighton), Dr. Harold H. B. MacLeod* (Shrewsbury), Dr. J. E. Kilvert* (Derby), Dr. G. Francis Smith* (Watford), Dr. Hugh Lawson* (Chislehurst), Dr. C. G. B. Kempe* (Salisbury), Dr. W. B. Maurice* (Marlborough), Dr. John Gay,* Dr. E. C. Morland,* Mr. D. J. G. Watkins* (Lincoln), Dr. Philip G. Laver* (Colchester), and Mr. W. H. Dolamore,* along with Dr. G. B. Hillman (Wakefield), Mr. Philip H. Cox, Mr. H. M. Hake (Director of the National Portrait Gallery), Mr. O. J. R. Howarth (Secretary of the British Association), Mr. S. Forrest Cowell (Secretary, R.C.S.), Mr. R. H. Burne (Physiological Curator), and Mr. D. K. Cassels (Assistant Secretary).

Sir Berkeley Moynihan proposed the toasts of The King and The Donor, remarking that there would then and in the future be no other toasts than these on the annual occasion, and, of course, no reply to them. He alluded to Mr. Buckston Browne's gift of Downe House to the British Association and said that some of the Darwin treasures were on view in the Conservator's room. He then bade the guests mingle, an Anglo-Saxon word which with its implications of frequency and intimacy aptly described the pleasant social intercourse which followed.

RECENT WORK ON HOOKWORM.

SOME SIGNIFICANT RESULTS.

WE lately commented in a leading article¹ upon an investigation by Clayton Lane into the diagnosis of hookworm infection. Twelve years ago he took up the position that there were so many infected persons—he estimated them at about 800 millions—that they could not receive individual diagnosis before treatment unless two conditions were fulfilled. The first of these was that diagnostic methods must be far advanced from the position they then held, and the interval has seen the evolution of his diagnostic technique of direct centrifugal floatation (D.C.F.), which is simple, cheap, and certain if a single female hookworm is normally ovipositing, and which is capable of mass usage at the rate of a quarter of a million specimens yearly for every two microscopists employed. Second, the procedure employed in hookworm campaigns of taking the laboratory to the stool must be replaced by the material-to-laboratory method used in every other branch of clinical pathology. This second requirement has been rendered possible for D.C.F. by two simple expedients: the stool must be kept under water and its temperature must not exceed 80° to 86° F., except for relatively short periods, whose extent and duration he did not

¹ THE LANCET, July 21st, p. 128.

determine. These conditions being observed equally good diagnostic results can be got with a stool weeks old as with a fresh one. A fundamental point needs emphasis. Clayton Lane's final conclusions are based on egg counts made, not by the method which he used uncontrolled in 1917 when he initiated egg counts as an essential part of a hookworm investigation, nor by the equally uncontrolled method of N. R. Stoll, for both these have emerged unsatisfactorily from controlled counts. He has used a modification of D.C.F. which careful controls of wide range have shown to be more accurate than any other at present available, and which other conditions have suggested as being near to accuracy.

The first large-scale hookworm campaign, using the stools-to-laboratory method, was Clayton Lane's in 1915-17. He used for the examination of over 33,000 persons about Darjeeling the crude diagnostic methods then available. A second instance of this procedure has now been reported by A. C. Chandler, using D.C.F. and sampling, by means of about 10,000 examinations, various areas over nearly the whole of India, with its population of more than 300 millions. All the examinations were made in the laboratory of the School of Tropical Medicine, Calcutta, to which samples were posted. In one detail Chandler altered the advised procedure. Instead of being submerged the faecal specimens were packed to the brim in tins and, because he noticed in his examinations normal-looking eggs only, Chandler concluded without using controls that there was no loss of eggs between collection and examination; he attributed this lack of development to the exclusion of oxygen. P. A. Maplestone, however, using the same tins in the same laboratory, has reported that a flange prevents complete descent of the lid, so that an air space about 2 mm. deep overlies the faeces in a filled tin, and his controlled counts show that in the first six days the number of the eggs in these filled tins is halved, those remaining being commonly embryonated, and free larvæ being occasionally seen. He found, too, that this development occurred in the superficial layers, and whether or not the faecal surface was deprived of contact with air. These counts, as he notes, were subject to the ever-present error inherent in Stoll's method. During postal transmission of such faeces gases of decomposition are apt to force off the lid with oozing of faeces, and, as Maplestone shows, escape of larvæ which must be expected sometimes to reach infectivity—a dirty, dangerous state of affairs which postal authorities are sure to forbid. Clayton Lane's original investigation had, however, shown that submersion in thymolised water appeared to meet this difficulty, so that it is likely to be used in other campaigns unless some better means of preventing gaseous fermentation is discovered.

Chandler's stool-to-laboratory survey constitutes a notable achievement and an impressive demonstration of the practical possibility of this procedure. His work draws attention to another point, already established but persistently disregarded. By D. C. F. he obtained an infection-rate twice as great as did J. W. Tomb using Clayton Lane's earlier technique of levitation. The conditions being apparently the same; while in a Darjeeling tea garden in which district Lane's microscopists had obtained with a centrifuged smear an infection-rate varying from about 40 to 80 per cent. according to the garden concerned, D.C.F. showed one of 90 per cent. in spite of repeated intervening treatments. Statements in original papers, or even in abstracts issued under impressive authority, which do not define the technique employed in estimating a local infection, are inexactitudes parading deceitfully in a cloak of pseudo-scientific accuracy. They teem in the literature.

The Distribution of Species.

The interesting and important question of species distribution has received recent notice. Apart from Calcutta *Ancylostoma braziliense*, for which *A. cephalicum* is a synonym, has apparently been found in man in India and Burmah when looked for. Its range, in animals at least, is world wide. *A. duodenale*

appears to form a pure infection in Egypt, and F. L. Soper has reported a nearly similar condition in a Paraguay village. About the Darjeeling hills *Necator americanus* infection seems to be even purer than it is in most parts of America. Should the ethnological explanation of these differences not bear closer examination they form a pointer to some biological factor perhaps capable of preventive use by man.

The Role of Animals.

The influence on human hookworm infection of animals dependent on man is varied. The pig, as R. M. Gordon notes, furnished Maplestone with three specimens of *A. duodenale*, and one worm which Gordon identified as *N. americanus*, but which exactly resembled specimens which Gordon obtained from pigs in Brazil. On morphological and biological grounds J. E. Ackert and Florence Payne in Trinidad separated the pig necator specifically as *N. suillus*. The morphological differences between this and *N. americanus* are of a minuteness equal to that which, according to the same observers, separates *N. americanus* as described by themselves from *N. americanus* as described by A. Looss. They should not be held specific in one case and not in the other. The biological tests were made with larvæ from untrapped cultures, and, as Clayton Lane has noted, these residual larvæ are perhaps those with least penetrative power, not average specimens, and that they did not produce infection may be explicable on those grounds. Of pigs examined in Trinidad 90 per cent. were infected with necator, and the pig must accordingly be held suspect as a "reservoir host" of this parasite and a disseminator of infection to man.

By eating and re-passing human faeces animals act as broadcasters of hookworm eggs. Chandler has obtained hookworm eggs from pig's faeces for three days after feeding the animal on egg-containing faeces. Cultures of the stool which first contained eggs after feeding produced many more larvæ than did cultures of the original stool; but again the cultures were untrapped, so that only the residual larvæ were counted. The lesson may be the opposite of that suggested. He finds that both dog and rat fill the same rôle. The influence of cattle lacks exact investigation, as does that of scarabæid beetles. Using cockroaches, he mentions an experiment in which 2 mg. of droppings from an insect fed on large numbers of hookworm eggs produced 110 larvæ, again, of course, from an untrapped culture, so that from the local numbers of these pests they must be active agents in producing a widespread soil infection in the Asansol Mines, Bengal. A good deal of incidental evidence is now accumulating as to animals forming unsuspecting baits for infective larvæ. After penetrating them larvæ shortly die and man is correspondingly safeguarded.

Light Infection.

Since Francis Bacon's time biology has rested on observation more or less controlled. For that proved procedure there is a tendency, particularly among non-medical writers on hookworm infection, to substitute a mathematical basis. An infection with a given number of hookworms is injurious, one with less is immaterial to the patient. C. W. Stiles has dealt with this "very definite, unambiguous, clinical advice based on definite unambiguous exact mathematical units," and he has emphasised, what after all every general practitioner could tell the hookworm worker, that men refuse in their reaction to disease to conform to mathematical formula, however impressive; so that, even if the lightest infections prove immaterial, there can be no exact mathematical group-limit between the material and immaterial ones. As for individuals, Clayton Lane has noted that tests employed must be both apt and exact. It leads nowhere to select a set of tests and, finding that they detect no difference between infected of a certain grade and non-infected, to state definitely that infections of that grade are immaterial. "It is as useless to attempt to measure entamœba with a foot rule,

whether obtained from Mr. Woolworth or from the Greenwich Observatory, as to record the hours of sunshine with the most delicate of barographs." A set of tests established by Stiles 13 years ago did show a difference between the same community before and after treatment. They dealt with such matters as underlie material contentment—strength to earn, freedom and recovery from illness, length of life. They were confirmed by Clayton Lane in 1916 and after this interval are again being applied, but hitherto without the exact basis of accurate egg counts, made to determine the degree of infection present before disinfection. Since these tests of energy, resistance, and recuperation have proved the most delicate hitherto employed, they or their like will doubtless be re-employed, checked by the exact diagnostic test now available, which alone can measure infections of that tenuity.

Unless the oviposition-rate of hookworms is fairly uniform, diagnosis in light infections cannot be certain. Mathematical aids have recently been called in to determine whether regular oviposition exists. H. W. Brown has pointed out that individual cyclical oviposition will produce a uniform tracing when worms are sufficiently numerous, provided, it may be commented, the cyclical condition is not due to change in environment acting equally on all worms. In the three cases he investigated the hookworms were estimated as numbering 13, 135, and 130. He laid considerable stress on figures derived from three-day and six-day running averages, that is, taking the last as an example, a comparison of the total eggs passed on days 1 to 6, with that on days 2 to 7, and so on through the whole series. But if individual, non-environmental cyclical oviposition do occur it will certainly be submerged in daily counts with 130 females laying, and it seems unreasonable not to conclude that it will be so even with 13; while with running averages of 3 to 6 days it must be wholly swamped. Here the mathematical aid invoked has proved illusory. Actually the presence or absence of cyclical oviposition can be determined only by daily counts from cases parasitised by a single female, and only D.C.F. is accurate enough to count these cases. Stoll's method used by Brown, even had it proved reliable within its limits, could not detect, much less count, an infection of this tenuity.

Migration of Larvæ.

Yet mathematics have a position in this biological problem. "Given ideal conditions of extra-corporeal development and of establishing contact with man, a single pair of hookworms is mathematically capable of destroying the human race within a year."² In other words, the degree of infection is of little hygienic importance, otherwise the tropics would be clear of man at this moment. It is the place and manner of defæcation, by the person with even a single pair of worms, which is significant. In our leading article already cited the proved migration of hookworm larvæ is mentioned, ease of progress determining its extent. The existence of migration has been denied on mathematical grounds, so few larvæ having been found at a distance from an infected spot. Yet mathematics show that if 10,000 larvæ reach a square inch of soil and thereupon space themselves uniformly on its surface one inch apart, they will cover a circle 4 ft. 8 in. in radius, so that the most perfect extraction will recover only one from each square inch of the soil within its circumference. If migration occur uniform recovery of such small numbers in uniform conditions would be evidence not of the restriction, but of the freedom of migration. But even if this free movement could occur all larvæ reaching the outer parts of the area would have traversed its inner portions, so that, whatever happens, the region about an infected spot must be the region of greatest risk. It follows that the more conscientious is the use of a latrine which does not prevent defectional infection,

the more generously does it infect. The importance of defectional infection has been most strikingly proved by Cort, Grant, and Stoll in China. Of soil samples collected round latrines infective hookworm larvæ averaged about 11 per sample, while of those from ground where vegetables had been fertilised with infected night soil they averaged only about three.

Carbon Tetrachloride.

It requires hardihood to suggest that the popular carbon tetrachloride treatment is neither safe nor certain, but Clayton Lane has lately marshalled the deaths which have followed its use, and some evidence of its inefficacy may be discovered in important footnotes to a paper by R. W. Hill. Over 100 persons were treated first by this drug and then by oil of chenopodium, the dose of each being 3 c.cm. Apparently 25 per cent. remained infected when re-examined by H. H. Willis's uncertain method. Of the infected, Stoll's method missed 6, estimated 25 as containing fewer than 500 eggs per gramme of faeces, and in three more gave counts indicating residual infections varying between 25 and 800 worms, according as different estimates of their egg-laying power are accepted. In other words, after administration of two drugs, each in a dose which has caused a considerable number of deaths, there were, if trichostrongylus infection can be excluded, residual infections of this extent. Confirmatory evidence of the failure and risk of carbon tetrachloride lies in B. M. Wilson's statement,⁴ that thymol had replaced it in Jamaica.

Carbon tetrachloride produces great fatty degeneration of the liver and sometimes of kidneys and adrenals. Administration is apparently a gamble on the occurrence of the usually rapid regeneration. It is the drug in present general use for the herd treatment of hookworm infection, that is for treatment on a mass scale without previous diagnosis, the procedure in such common use. Clayton Lane at Cardiff gave his studied reasons for the belief that with diagnosis so rapid and certain, the "persuasion" of backward races to accept herd treatment had no justification in mortality, science, or expediency, and that to use for it a drug which sometimes proved fatal in a smaller dose than that in habitual use for herd treatment was devoid alike of reason and humanity.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Health of the Free State.

THE report of the Department of Local Government and Public Health of the Irish Free State for the year ending March 31st, 1927, was issued a few days ago. It is remarkable that the census of 1926 now gives a trustworthy basis for the calculation of local death-rates, and has been of much service to public health administration. The larger town districts in the year under review show a death-rate from all causes of 15.5 per 1000 of the population. There has been a gratifying improvement since the year 1916, when the town death-rate was 19.3 per 1000. Part of this improvement is attributed to the better housing conditions of the people to-day. Typhus is being gradually eliminated, and there has been a signal reduction in enteric fever. In every county, however, advance is hampered by financial considerations. The total number of attendances of out-patients at the treatment centres for venereal disease in Dublin was 26,598; in 1922-23 it was 22,230, and in 1925-26 it was 29,315.

The Local Appointments Act.

In the Dail last week President Cosgrave moved that a select committee of 11 deputies should be appointed to inquire and report whether, having

² Brit. Med. Jour., August 4th, p. 193.

³ Ibid.

⁴ Ibid., p. 207.

regard to the experience gained in the working of the Local Authorities (Officers and Employees) Act, 1926, any amendment of that Act was desirable. It will be remembered that by the Act the power of election of officers of local authorities was taken from those bodies and the choice of persons to be appointed to each position was entrusted to a Local Appointments Commission, which normally acts on the advice of a Selection Board. Many medical men welcomed this change, because it took the appointment to medical posts out of an atmosphere of political and family influence, if not because it was a step in the direction of a State-controlled service with entrance by competitive examination. As far as medical appointments are concerned the Act has worked without any cause for complaint, and there is no doubt that a better class of candidates is now attracted to the public service. If any change is made as the result of the inquiry by President Cosgrave's committee it is to be hoped that the change will be a step farther in the direction of central control, rather than of restoring power to the local bodies.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The Local Government Reforms.

THE Secretary of State for Scotland and the Under Secretary have both been much occupied on the platform and with deputations for the last two months. The reception of the new local government proposals is critical and slow. The great health authorities are favourable, but the education authorities are largely antipathetic. Major Elliot made a good point in a speech reported as follows:—

"It was said that it meant an invasion of Scottish rights and an attack on Scottish local government. It seemed to him to bear in the opposite direction. The new county authorities and town councils controlling education and poor relief and all matters of local government would have a responsibility and power which were never possessed by local authorities in Scotland before. To unify the local authorities in Scotland and produce 30-odd great bodies was to produce bodies far more capable of standing up to the departments in Edinburgh or even to the Imperial Parliament than any local authority which they had ever seen in Scotland before."

In the process of devolution of administrative work, strong local authorities are a necessary counterpoise to the insistence of a central Government bureaucracy.

A Campaign for Health.

The Combe Trust has done many good things in the last two generations, and has now made possible a useful series of "talks" at the Edinburgh Y.M.C.A. lecture hall. The first was given by Dr. Chalmers Watson on The Doctor, the Individual, and the State. Dr. Watson always speaks with moderation and knowledge, and he was right in saying that "the development of a campaign for health would bring the numerous campaigns against disease—cancer, rheumatism, tuberculosis, heart disease, &c.—into a truer and wiser perspective." For these reasons he believed that the work of the recently constituted Scottish Health League merited the keen interest and support of the community.

The second talk of the series was given by Lieut.-Colonel J. du P. Langrishe, lecturer in Public Health in the University of Edinburgh, who took as his subject the Influence of Sunlight on Health.

I learn that a plan of campaign is being prepared for the Scottish Health League, the headquarters being the Usher Institute of Public Health. The new health museum that has grown up under Prof. Leaban's unstinting energy is one of the best things to be seen in any Scottish medical school. It indicates a first-class conception of health object-teaching.

Sir Auckland Geddes on Education and Physique.

As Minister of National Service during the war, Sir Auckland Geddes has more knowledge than any other man of what the country suffered from defective physique, and he drove home the lesson in his address to the Philosophical Institution the other day when he spoke of education from the three stand-points—racial, physical, and mental. He would never forget, he said, the horror which struck him when he had to face the figures of the total men of military age in the country as contrasted with the total of men of military age who were fit. The difference—and he chose his word carefully—was appalling. He knew that a great deal had been done since, and was being done, but in many towns and villages and in the scattered cottages of the countryside, the physical side remained as hopelessly inefficient to-day as it was before the war. He declared—and the facts are only too true—that he could take his audience to cottage homes where the mental condition and health knowledge of mother and father were mediæval, where they dared not send for medical men to see their children, because they were already in debt to the local practitioner, and would not add to this indebtedness.

The address as a whole was an impressive plea for better adapted schools, for a high individual education, and above all for education in health and the production of personal fitness. It is gratifying to those who have given a life-time to these causes to hear a man of Geddes's force justifying our day's work from another standpoint.

Ultra-violet Light.

The Edinburgh child welfare centres are already well provided with lamps; but now the city has made a new departure: the Portobello Baths are fitted with appropriate lamps for all that wish to use them—on terms. The important fact is that the lamps are under skilled medical direction.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. (D.) L. V. Donegan to Virid for R.N. Barracks, Devonport.

ROYAL NAVAL VOLUNTEER RESERVE

Proby. Surg. Sub.-Lt. H. L. Hoffman to be Surg. Sub.-Lt.

ROYAL ARMY MEDICAL CORPS.

Maj. J. T. Simson is re-empld. under Art. 507 (b), Royal Warrant for Pay and Promotion, 1926.

Lt. E. W. Hayward and Temp. Lt. J. E. Stokes resign their comms.

ARMY DENTAL CORPS.

Lt. D. W. N. Squires to be Capt.

ARMY RESERVE OF OFFICERS.

E. W. Hayward to be Lt.

TERRITORIAL ARMY.

Maj. J. K. Lund to be Lt.-Col. and to comd. the 125th (E. Lan.) Fd. Amb.

Maj. R. Coffey, having attained the age limit, retires and is granted the rank of Lt.-Col., with permission to wear the prescribed uniform.

Capt. L. A. Wilson, having attained the age limit, relinquishes his commn. and retains his rank.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Capt. G. S. Phillips, from the Active List, to be Capt.

ROYAL AIR FORCE.

Flight Lt. (Hon. Squadron Leader) C. A. Meaden resigns his temp. commn. and is permitted to retain the honorary rank of Squadron Leader.

INDIAN MEDICAL SERVICE.

Madhavrao Subrao Katre to be Temp. Lt. Temp. Capt. relinquishing their comms.: Jatindra Mohan Dutta Gupta (and retains his rank), Jatindra Mohan Benerjee, Krishna Chandra Varma (and retains his rank), Lt.-Col. P. M. Rennie and S. A. Ruzsak retire.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

The following are 1927 statistics of three cities:—

Name of district and estimated mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Diarrhoea, &c., under 2 years.	Maternal mortality from childbirth.
Newcastle-upon-Tyne (288,500)	18.7	12.4	1.39	1.19	2.5	1.7	88/41	9.4	3.7
Salford (247,600)	17.3	13.9	1.66	1.27	3.5	1.5	81/—	15.6	3.7
Portsmouth (232,100)	17.1	12.7	1.00	1.53	2.1	2.2	55/24	3.5	4.5

The death-rates of pre-school (1-5 years) children per 1000 births were: Newcastle-upon-Tyne, 44; Salford, 50, Portsmouth, 42.

Newcastle-upon-Tyne.

Dr. Harold Kerr reports that the coal trade was extremely flat, but that a slight revival in shipbuilding eased unemployment to some extent. The expenditure on poor relief was £383,460 as compared with £486,374 for the previous year and £401,024 for 1925. The year 1927 was cold and grey with a miserable summer. The hours of sunshine were 899 as compared with 1085 in 1926. The atmospheric pollution gauges indicate less tarry matter in the industrial areas than in the residential areas. The "chief sinners" among the factory chimneys belonged to the corporation, but have improved somewhat, although more grit is produced from the tramway's chimney. A regional smoke abatement committee is endeavouring to find a common policy for Tyneside, but finds it difficult to get all the different authorities into line.

An effort has been made to follow up cancer cases, and now that the University has formed a branch of the British Empire Cancer Campaign this investigation promises more success. There were 116 notifications of small-pox with no deaths. Contacts, with the exception of tramps in two lodging-houses, readily accepted vaccination. Diphtheria was relatively less frequent, but the type was more severe, the case-mortality being 7.1 per cent. Encephalitis lethargica has shown a gradual decline since 1924, but of the 21 cases notified in 1927 only one recovered, while 11 died and 8 were rendered incapable of employment by mental or nervous impairment. In May immunisation of the City Hospital staff was adopted both for scarlet fever and diphtheria, and since then no further cases have occurred among them. The beds are now used for a variety of diseases. Thus the admissions included 173 cases of pneumonia, 63 of measles, 55 of erysipelas, 13 of encephalitis lethargica, and 12 of cerebro-spinal fever.

There were 362 new cases of syphilis and 525 of gonorrhoea at the V.D. clinic as compared with 290 of syphilis and 483 of gonorrhoea in 1926. The attendances per case are now 17.5, but 41 per cent. of the patients cease attending before completion of treatment. There were 58 notifications of ophthalmia neonatorum, all of whom recovered. Of 401 registered blind persons, 76 are said to have been blind from birth, but only two are under 5 years of age, and of these one was not born in Newcastle and the other had a congenital malformation of the eye. The decline in diarrhoea (the deaths in 1927 were fewer than ever

before) is claimed by Dr. Kerr as a proof of a much better informed motherhood. The babies, however, suffered much from respiratory diseases during this sunless year, in spite of the relative absence of whooping-cough and measles. Dr. Kerr points out that neither the neonatal nor the maternal mortality has declined appreciably during the present century in Newcastle, but that fortunately the mortality from puerperal sepsis is low in Newcastle. The antenatal clinics were attended by 1047 mothers, while the total births were 5395. The infant mortality-rate was 119 in All Saints ward and only 38 in Heaton ward. Attendance at confinements was shared equally by medical practitioners, midwives, and the Princess Mary Maternity Hospital. Free milk is now only distributed to the very poorest; even so, 18½ tons of dried milk were distributed free, while 21 tons were delivered at cost price. The increased attendances at the 11 welfare centres makes the provision of more medical sessions urgent. The babies' hospital and mothercraft centre is doing good work for babies suffering from wasting and other chronic conditions, and its grant from the health committee has been increased. The death-rate from tuberculosis, although very high, is lower than it has ever been before in Newcastle and is one of the lowest in the district. Tyneside apparently suffers from a particularly virulent and rapid type of the disease, and in consequence it is difficult to keep the sanatorium beds fully occupied, whereas there is a waiting-list for the "advanced" beds. Workshops for occupational therapy are being established at Barrasford Sanatorium.

Out of 376 milk samples examined for tubercle 14, or 3.7 per cent., were found to be infected. The 334 milch cows stalled within the city are examined at least four times in the year and among them six tuberculous animals were found. Some of the private slaughter-houses are in a "shockingly bad" structural state and there never was a greater need of a public abattoir than at present. Of 188 samples of milk examined for excremental pollution, 40 per cent. were found to be dirty. Between June and September the percentage of dirty milks was 73, and Dr. Kerr comments that there is plenty of room for clean milk competitions and similar efforts. He also points out that two exceedingly well-constructed automatic machines selling milk in pennyworths have been set up in poorer parts of the town and "have been the means of distributing excellent milk in first-class condition."

There is still a vast amount of overcrowding which shows no signs of lessening, although the corporation's contribution during the year to the housing shortage after allowing for "compensatory" houses was 1536. Dr. Kerr gives a cheering account of the manner in which the tenants of the three condemned areas have settled in the houses provided for them in the outskirts and are taking pride in their gardens. There was, it is true, a small residue of confirmed slummers, who had to be evicted and with whom nothing could be done, and a few of the new colonists make no attempt to furnish their houses and will probably drift back to the slums; but "there is no question that the municipal housing has had a wonderful effect in raising the domestic tone of large numbers of the submerged tenth."

Salford.

Dr. H. Osborne shows that there was an increase of 358 deaths over the number occurring in 1926, when the Salford death-rate was the lowest recorded (12.4). The following were some of the principal increases during 1927: influenza 79, pneumonia 74, tuberculosis 31, nephritis 29, violent deaths (excluding suicide) 34, and heart disease 131. Since 1920 the birth-rate has declined year by year from 27.3 to 17.3. The infant mortality-rate of 81 is the lowest ever recorded, and may be compared with the rate of 207 for the quinquennium 1893 to 1897. The work of the maternity and child welfare department is being seriously impeded in the Broughton district by the want of

adequate premises, and the desirability of setting up a combined child welfare and school centre is urged. The maternity home and babies' hospital has at present ten beds for mothers and 18 cots for babies. Many applications for confinement have to be refused, and Dr. Osborne presses for the present building to be devoted to the increased number of 15 maternity beds and for a new building to be erected for the babies' hospital on an adjoining site. All cases booked for the maternity home are invited to attend a special antenatal clinic. The mothers very much appreciate the antenatal clinics and the midwives coöperate well. The babies' hospital does good work in treating cases of marasmus and malnutrition. The artificial light installed in 1926 has proved beneficial, and it is specially noted that the simplest methods of feeding, which can easily be continued by the mothers after discharge, have proved the best for marasmic infants. Some remarkable photographs are given of marasmic infants before and after treatment and are stated to be by no means exceptional cases. The maternity and child welfare scheme includes nine welfare centres and two special treatment clinics. Massage is provided at several centres and has been found useful. Of the 4301 births, 3051 were attended by midwives, who sent for medical help in 1254 cases. The 47 babies, who suffered from ophthalmia, four of which were classed as "very bad" cases, four as "bad," and six as "fairly bad," all recovered without injury to sight. Additions made to the window displays at the health offices included an exhibit on dental hygiene loaned by the Dental Board and another dealing with the prevention of rickets. The Nab Top Sanatorium, which could not be kept full with early cases of tuberculosis, has been profitably used for an increased number of children with early and sometimes indefinite signs of the disease, and an open-air school is being erected for their education. In January, 1927, Dr. G. J. Crawford was appointed "whole-time" city bacteriologist. An improvement scheme affecting 75 houses and 337 persons has been approved for a congested area in the Greengate district. The area will not be used for dwelling-houses, and houses on another site will be provided for the displaced tenants.

Experiments have been continued with smokeless fuel. There are now over 40 "Salford" grates in the Health Department burning vertical dry coke, and similar grates in the hospitals and municipal lodging-house, and it is found that for equivalent heating the cost of these dry coke fires is only half that of coal fires. Coalite has also been found satisfactory, and it is hoped that its price will shortly be reduced. The trouble with ordinary gas coke is that it is waterlogged. The experiments carried out as to the heating effects of the various fuels are fully described. Interesting comparisons of the amount of tar and soot, as an indication of domestic smoke pollution in Salford, Marple, Liverpool, and Southport are given. Although the total deposit from the atmosphere in Liverpool exceeds that in the central part of Salford, the tar and soot deposit is 20 per cent. higher in the case of Salford. Observations have also been carried out to ascertain the variations of the amount of "sunlight" available as distinguished from "bright sunshine." The method adopted was to expose an acidified solution of potassium iodide and to measure the milligrammes of iodines liberated by the light. The observations have been carried out daily for two years at four stations, namely: (1) Regent-road, in the centre of Salford; (2) Nab Top, Marple, about ten miles to the south-east; (3) Ladywell Sanatorium, in the western suburbs; and (4) Drinkwater Park Hospital, four miles to the north-west. The results were somewhat surprising. A summary of the two years results shows that Drinkwater Park was 16 per cent., Nab Top 11 per cent., and Ladywell Sanatorium 10 per cent. better than Regent-road. The tar and soot deposit at Marple is double that of Southport, and Dr. Osborne suggests that it is sufficiently near the Manchester group of towns to receive the drift of

The municipal common lodging-house—"Salford House"—is evidently appreciated, as its beds were 95 per cent. occupied during the year, whilst the beds of the other common lodging-houses were only 66 per cent. occupied. There are only 115 milch cows housed in the city, but amongst these two tuberculous udders were found during the year. As regards outside milk, 371 samples were examined for tubercle and 31, or 8.3 per cent., were found to be infected. So far, it is pointed out, the new legislation has produced no improvement in the milk-supply as regards tuberculosis. The very interesting report of the public analyst shows that the Salford Corporation continues its strenuous efforts to circumvent food fakers.

Portsmouth.

Dr. A. Mearns Fraser gives particulars of the present state of the housing problem. During the five years before the war the annual average of new houses was 760. During 1914-18 the number was 160. During the last six years the number of new houses has been 274, 162, 221, 421, 682, and 898 respectively. Of the 898 built in 1927 only two were municipal, but 272 municipal houses are nearing completion. The dock-yard employees are forming a public utility society to erect 160 houses. At the present rate of building, all who are able to pay a rent of 10s. to 15s. will be provided for at no distant date. During 1896 to 1914 the corporation demolished over 500 unfit houses and removed the worst slum area. The next worst area is now being cleared and the old buildings replaced by modern two-storey tenements. Dr. Fraser goes on to deal with the remaining difficulty—namely, 500 old cottages and houses quite worn out and unfit for habitation, let at rents mostly varying from 3s. 6d. to 6s. 6d. per week. Most of these tenants want better accommodation, and a considerable proportion could pay a higher rent. Dr. Fraser describes the scheme, which was approved by the city council in December last. Sites have now been approved and an excellent lay-out and plans for 153 houses and 12 flats have been prepared. When this instalment has been completed some of the worst of the 500 can be dealt with. As accommodation for the dishoused tenants is made available the old houses will be closed and demolished under Part I. of the Housing Act, 1925. The new blocks will resemble some already built consisting of two self-contained houses and four flats, but smaller tenements will be provided for single persons and families of two only.

In allocating, families with children will be given the self-contained houses or the tenements on the ground floor. It is estimated that if the houses do not cost more than those at present being erected and the rents average 8s. a week the annual loss will be just over one-third of a penny rate, but if, as is probable, a proportion of the tenants cannot pay the new rents further assistance in some form or other will have to be afforded from the rates. It is not likely that the loss will thus be more than doubled and even if it is, Dr. Fraser considers the expenditure justifiable for this public health measure of first-class importance. Examples are given to indicate the deplorable conditions prevailing in these old houses.

Scarlet fever antitoxin was used for 251 cases in the hospital with satisfactory results. The need for beginning the treatment at an early stage of the disease is emphasised.

A chart brings out the fact that whereas formerly 1 out of every 6 babies died in the first year of life, now only 1 out of every 10 dies. The scheme by which pregnant women can for a fee of 5s. ensure payment for the services of the doctor, who may need to be called in by the midwife, has been widely used. The total net cost to the local authority for the services of doctors called in by midwives during 1927 was £508, and the cost in the year preceding the scheme was £511. Under the insurance scheme the local authority paid 48 per cent. of the doctors' fees, whereas in the previous year the local authority paid 68 per cent.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 27TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 148 (last week, 128); scarlet fever, 3101; diphtheria, 1354; enteric fever, 64; pneumonia, 1047; puerperal fever, 31; puerperal pyrexia, 104; cerebro-spinal fever, 3; acute poliomyelitis, 13; acute polio-encephalitis, 1; encephalitis lethargica, 25; continued fever, 1; dysentery, 8; ophthalmia neonatorum, 103. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Oct. 30th-31st was as follows: Small-pox, under treatment 8, under observation 1; scarlet fever, 2690; diphtheria, 1858; enteric fever, 31; measles, 76; whooping-cough, 277; puerperal fever, 20 (plus

10 babies); encephalitis lethargica, 69; poliomyelitis, 3; "other diseases," 22. At St. Margaret's Hospital there were 16 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 1 (1) from enteric fever, 7 (1) from measles, 10 (2) from scarlet fever, 22 (7) from whooping-cough, 29 (1) from diphtheria, 76 (26) from diarrhoea and enteritis under two years, and 76 (17) from influenza. The figures in parentheses are those for London itself.

Two fatal cases of measles were reported from Liverpool and 4 fatal cases of scarlet fever from Leeds. Nottingham reported 3 fatal cases of diphtheria. The deaths from diarrhoea and enteritis under two years are now diminishing; Liverpool reported 7, Manchester 6, and Sunderland 4. The deaths from influenza are beginning to rise.

The number of stillbirths registered during the week in the great towns was 235 (corresponding to a rate of 36 per 1000 births), including 47 in London.

"Audi alteram partem."

A RADIUM-PLATINUM ALLOY.

To the Editor of THE LANCET.

SIR,—I note in your last issue (p. 932) a short description of an alleged discovery by Dr. Max Heiner, reported from a medical congress at Hamburg. The same wonderful discovery has previously appeared in a more extended form in the lay press and the same claims are made—namely, that an alloy is produced of radium and platinum. Any chemist of but slight experience will at once query the existence of such alloy, as metallic radium is a curiosity. Radium as a metal is like sodium, practically non-existent in the free state, soon oxidising in the presence of water vapour to radium hydroxide.

Let us grant for the moment that Dr. Heiner has produced an alloy of radium and platinum. The next claim is that pointed cylinders are made up and "when introduced into the body radon diffuses into the surrounding tissues and disintegrates intracellularly: so that biological effects are to be expected not only from the gamma rays, but also from the much more potent alpha and beta rays." A beginner with the slightest knowledge of the physics of radium well knows that the alpha rays can be screened by a thin piece of paper. With a dense metal like platinum in an alloy with radium the amount of alpha rays given off from the mere outer skin surface of this needle will therefore be almost nil. Similarly the radium emanation itself will be screened off except from the extreme outside of any metallic alloy. In the classical experiment of Rutherford and Roys to determine the chemical nature of alpha rays the thickness of the glass capillary tube allowing their passage under pressure was 0.01 mm. The light diffusible gas, helium itself, did not pass; only the stripped nuclear portion of the atom went through, devoid of planetary electrons, in a nascent state. With platinum, density 21.5, compared with glass, 2.6 (comparative density thus 8.3 to 1), it seems theoretically impossible for any appreciable amount whatsoever of radium emanation to be given off.

Next, as to the beta rays, these in most instances are objectionable and caustic, and indeed would be very variable in amount, being filtered from the centre and all other parts, to the periphery of the alloy needle. Twenty years ago Dominici (*Bulletin de l'Association Française pour l'Étude du Cancer*, Tome 1, No. 1, 1908 (Felix Alcan)), in his original and profoundly accurate description of radium treatment by gamma rays, realised the idea of exact filtration, and the gamma ray treatment, which is all-essential, can only be carried out by scientifically exact primary filtration with platinum shutting off alpha and beta

rays varying in filtration thickness according to where the individual radium particles were situated in the depths of the needle.

Furthermore, with the standard method of radium therapy, protected by platinum or other appropriate and dense metals, the radium element is contained in the interior of the screen or needle and the important radio-active mineral is preserved for thousands of years, while the screen when worn may be replenished when required. In the case of a "radium alloy," in the course of a few years, from actual application and frictional wear and tear, not only would the platinum be worn down, but the granules of precious expensive radium interspersed with the platinum would become dispersed and needlessly lost.

I should be pleased to hear the opinions of scientific workers on this question, but as at present reported, this "radium-platinum alloy" appears to me to be a definite retrograde step which is likely to act as a set-back to accurate dosage treatment with radium, which is even now little understood in our country except by specialist radium surgeons.

I am, Sir, yours faithfully,
SPENCER MORT, M.S. Glasg., F.R.S. Edin.,
(Lt.-Col.); Surgical Director, North Middlesex Hospital.

North Middlesex Hospital, Edmonton, N.,

THE "RANGE OF UREA-CONCENTRATION" TEST.

To the Editor of THE LANCET.

SIR,—In Dr. T. C. Hunt's article on this subject in your last issue there are a number of points with which I am hardly in agreement.

Writing of "small white" and "small red" kidneys, he says:—

"In the first the urea range shows a parallel diminution with that of the maximum concentration, in the second a poor 'MacLean figure' is accompanied by a relatively good range—i.e., a high 'urea index.'"

Also—

"The urea index is seen to bear a close inverse proportion to the degree of nitrogen retention: under 12 it is always associated with a blood-urea above normal, while above 25 it appears to suggest the 'small red' rather than the 'small white' kidney, and to be strong evidence against the presence of any but very slight retention."

First of all, I think most practitioners take the term "small red kidney" to mean the granular or primary contracted kidney—the so-called primary chronic interstitial nephritis (Gaskell)—and associate with it a serious condition in which nitrogen retention is marked. Although Dr. Hunt does refer to this "small red" kidney as the "benign essentially arterio-sclerotic kidney" he is apt to cause confusion in the minds of some by leading them to think that cases which they have been taught to regard as serious, especially when "MacLean's figure" is below normal, may have normal nitrogen retention and a

relatively good prognosis. The class of case to which he refers is, I think, the same as that mentioned by me in the paper on the above test under the heading of hyperpiesia (Case 4 and another)—arterio-sclerotic kidneys—a clinical group in which the brunt of the disease seems to have fallen on the vascular system, the kidney substance suffering in so far as its vessels are affected (nephro-cirrhosis arterio-sclerotica) and generally revealing little or no loss of function. As it is not possible satisfactorily to correlate the signs and symptoms of kidney disease with the underlying pathological condition it is preferable to base our diagnoses or classification on the results of function tests, and in doing this to give the fullest consideration to the state of the cardiovascular system and to other factors having a bearing on the kidneys.

In publishing the test I was careful to avoid any such formula as the "urea index," preferring to leave the "maximum" and "minimum" values as a ratio. All the modern work on oedema shows that water excretion is not only dependent on the condition of the kidneys and the circulation, but also on the state of the plasma and tissues—on the protein osmotic pressure of the plasma, &c. This is one reason, especially in subacute parenchymatous (hydræmic) nephritis why it is inadvisable to use the "urea index"; the ratio itself is all right. The value of water as a test does not run strictly parallel to that of urea concentration as a test, but in any case the figure for dilution enhances the value of that obtained for concentration. For example, in marked hydræmic nephritis a ratio of 4.2/4.0 is quite an ordinary result. The "urea index" would be 4.8. According to the above quotation from Dr. Hunt's paper this always means a blood-urea above normal. We know, however, that in such cases the blood-urea is seldom raised. Again, are we to infer that such an index of 4.8 is of worse omen than one derived from the terminal stages of chronic interstitial (azotæmic) nephritis with a ratio of 1.3/1.1 (index = 15.4)? A much truer interpretation is obtained by applying my original remarks to the ratio: "taken conjointly the lower the maximum concentration and the more restricted the range the worse the prognosis." Urinary tests of function, anyhow, have a very limited value in acute or subacute kidney conditions where oedema or hydræmia is present.

It is not correct to designate as "MacLean's figure" the maximum obtained in the range test, as in some instances where this is low one may be dealing with kidneys that are over-sensitive to urea as a diuretic and in MacLean's test may pass more than the stipulated volumes in the various hourly periods. If by repetition of the latter test the amounts are still excessive a calculation must be made to allow for such dilution. The range test avoids this trouble.

The point raised by Dr. Hunt about the collection and examination of samples over longer periods in the water-excretion part of the test was considered afresh when R. S. Allison brought up the matter at the Royal Society of Medicine in November, 1925. I do not think there is any advantage to be gained by prolonging the test for more than three hours (at the most four hours). If the urine is collected hourly for these three hours one has sufficient evidence of the diluting power of the kidneys to make a comparison with the concentrating power. Indeed, bearing in mind what has already been said about the part played by factors other than the kidneys in water excretion it is not unlikely that prolonged and elaborate investigations with the water test may, unless great care is taken, lead to wrong conclusions. The normal response to 30 oz. of water taken on an empty stomach is that polyuria occurs within one-half to three-quarters of an hour when it reaches its maximum and then sinks rapidly. The bulk of the fluid is excreted within three hours. In damaged kidneys the polyuria is delayed and the total volume is reduced. Accordingly the only alteration I wish to make in the test (*Brit. Med. Jour.*, 1925, i, 64) is the substitution of the collection of urine for three hourly periods instead of for two hours. Indeed,

one would make little or no mistake if one kept to the two-hour specimen as described, but perhaps the amendment is better. Finally, with reference to post-mortem findings that occasionally seem at variance with the results of the test one should not be too ready to condemn the latter—on the contrary, one should rely rather on ability than appearances. Besides, in "nephritis" other organs and tissues are involved and sometimes may be as much if not more at fault than the kidneys.

I am, Sir, yours faithfully.

E. G. B. CALVERT.

Harley-street, W., Nov. 6th, 1928.

DEATHS UNDER ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—The suggestion made by Dr. Clausen in his letter of Oct. 27th regarding the Trendelenburg position in spinal analgesia is a very important and valuable one in cases where the blood pressure and pulse-rate are alone affected. If in addition to low blood pressure and increased pulse-rate there is depression of the respiration and cyanosis, as in the case reported, the Trendelenburg position will not only hamper the function of the respiratory organs by the pressure of the abdominal contents against the diaphragm, but also further impede the action of the right heart by an excess of venous blood from the abdomen and lower limbs. In these circumstances, I suggest that a change to the Trendelenburg position may precipitate disaster.

I am, Sir, yours faithfully,

Aberdeen, Nov. 3rd, 1928.

J. ROSS MACKENZIE.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

OPENING OF NEW SESSION.

THE last session of the present Parliament was opened by the King in State on Tuesday, Nov. 6th. In the course of the gracious speech from the Throne His Majesty said that the estimates for the Services in the coming year, which would be laid before the House of Commons in due course, were being prepared with strict attention to the continuing need for economy in public expenditure. The situation in the mining areas continued to engage the earnest attention of the Government who were taking energetic steps to promote the success of the scheme of industrial transference and migration. The abnormal expenditure out of the Unemployment Fund entailed by the displacement of labour from the mines would render necessary an increase of borrowing powers, and a Bill dealing with this question would be laid before Parliament. Measures would be presented to both Houses for giving effect in England, Wales, and Scotland to the comprehensive scheme which had been prepared by the Government for the reform of the rating system on a more equitable basis, for the reorganisation of local government, and for the readjustment of the financial relations between the State and the local authorities. The proposed changes in local government and in the relations between the Exchequer and the local authorities were measures of far-reaching importance. The Government anticipated that they would enable better provision to be made for the health of the people and would direct assistance particularly to those areas whose needs were most pressing.

HOUSE OF COMMONS.

TUESDAY, NOV. 6TH.

DEBATE ON THE ADDRESS.

During the debate on the motion that a humble address should be presented to His Majesty thanking him for the gracious speech from the Throne,

Lieut.-Colonel FREMANTLE said he hoped, by the help of all well-wishers of factory and workshop legislation on both sides of the House, that they might well be able to find time before the end of the present session for the passing of the now much-needed and frequently promised Factories

and Workshops Bill. The anticipation in the King's speech that the proposed changes in local government would enable better provision to be made for the health of the people was not encouraging to those who were keen on this or that particular measure of social progress. Still less was the fact that there was no mention of housing at all in the speech an encouragement. They had heard nothing that afternoon in regard to the question of the removal of the housing subsidy, yet it was vital to the housing movement to economise their resources as much as possible, and there was no question that a great deal of the subsidy on houses with a rent of over 1 guinea a week was being thrown away at the present time. The Prime Minister had stated that Parliament would have to deal with the Rent Restrictions Acts in the Expiring Laws Continuance Bill. Those Acts were at the very bottom of their difficulties in connexion with slum property and slum clearance. The development of estates was being delayed because of the exceptional instances of control. Here and there control had held up the erection of houses and had got in the way of development. It was causing inequalities to owners, unjust profiteering on the part of tenants as opposed to subtenants, and a great deal of suffering to subtenants. The Departmental Committee which dealt with this matter, and which represented the Labour Party as well as other parties in the House, recognised the inequalities of the Rent Restriction Acts and control, and recommended a good deal of decontrol. There was abundant reason why the subsidy should be further knocked off houses of the highest rental value. Decontrol and desubsidising were imperative simultaneously. By removing the subsidy on the more expensive houses, which were being adequately provided by private enterprise, much money would be set free by which they would be able to subsidise slum clearances. There was no promise in the speech that the subject of slums was to be dealt with. The Prime Minister said, in December, 1924, when he took office: "We have got to get rid of two things—the shortage in houses and the disgrace of the slums." He (Colonel Fremantle) believed that if they achieved decontrol and desubsidising they could have improvements in the slums.

The report of the Lunacy Commission, which was issued three or four years ago, revealed a system which was insufferably hard on a large number of mental cases. He sincerely hoped that time might be found for legislation on this subject. Referring to small-pox, Colonel Fremantle said that the country was suffering at the present moment from a vast outbreak of preventable disease—small-pox. It had been a mild type of that disease, but the medical profession could give no assurance that it would not become worse. They were sitting on the top of a volcano. He was glad that the great Powers had agreed, under the aegis of the Health Organisation of the League of Nations, to study the question of small-pox. A committee had been formed to study it permanently. Our own country was condemned as being one of the most infected with small-pox of all the civilised countries of the world. It was recognised that we were more behindhand in the application of vaccination than any other country, and other countries recognised the necessity for keeping up their quarantine regulations against us. Vaccination had hitherto been left in the hands of the poor-law guardians, while small-pox was in the hands of the sanitary authority. He hoped that in the reorganisation of local government it would follow, as a result of the Government's scheme, that the matter of vaccination would be under the control of the larger authorities.

Mr. BALDWIN (Prime Minister) said that he regretted that, owing to the overriding necessity of devoting the time of Parliament to the passage of the rating reform proposals of the Government, it would not be possible to deal with the Factories Bill.

SWINEY PRIZE FOR WORK ON MEDICAL JURISPRUDENCE.—The next award of this prize—a silver cup of the value of £100 and money to the same amount—to the author of the best published work on Medical Jurisprudence will take place in January, 1929. The award is made jointly by the Royal Society of Arts and the Royal College of Physicians, and any person desiring to submit a work, or to recommend any work for the consideration of the judges, should do so by letter addressed to the secretary of the Royal Society of Arts, John-street, Adelphi, London, W.C., not later than Nov. 30th.

ROYAL EDINBURGH HOSPITAL FOR INCURABLES.—The managers are considering a scheme of rearrangement of wards, which would enable additional accommodation to be found for women patients, the existing pressure being officially described as "very distressing." Last year, out of 247 applications for admission, only 128 could be accepted, and many of the applicants die before accommodation can be found for them.

Obituary.

SIR HUGH KERR ANDERSON, M.D. CAMB.,
F.R.C.P. LOND., F.R.S.

Sir Hugh Anderson, Master of Caius College, died on Nov. 2nd at the age of 63, and the University of Cambridge thus loses a man whose services were of exceptional importance. A laboratory worker by choice and training, he became by force of circumstance an administrator, and besides the individual influence which he had always possessed, he came to have a general influence on the trend of education in this country. As initiator and negotiator of large policies he had difficult tasks to perform, but for him the sequel to new responsibilities was always an enlarged circle of respect and friendship.

Hugh Anderson came of the well-known family of ship-owners, his mother being a daughter of Surg.-General John Murray. He was educated at Harrow, where he was Sayer Scholar, and on going up to Caius College with an entrance scholarship he took a first in both parts of the Natural Sciences Tripos. Preferring scientific labours to the more lucrative business of shipping, he studied medicine at St. Bartholomew's Hospital, graduated as M.B. in 1891, and returned to Cambridge to work in the physiological laboratory. Until 1905, partly in conjunction with the late Prof. J. N. Langley, and partly alone, he pursued those researches which still form the classical description of the physiology of the sympathetic system in its relation principally to the eye and the pelvic viscera. Much of this investigation, which forms the substance of 28 papers in the *Journal of Physiology*, consisted in counting the number of degenerated and undegenerated nerve-fibres in a single nerve-trunk; for this purpose a short length of the nerve, stained by osmic acid, was teased out, each individual fibre being ranged alongside its fellow on the slide. At such work Anderson, like Langley, was a master, and he was also a very fine operator. His criterion of a proper operation for the excision of a stellate ganglion in the kitten was that it should be done without the shedding of a single drop of blood, and he was an expert in the use of special staining methods. Towards the end of his time in the laboratory he became interested in the histology of the spleen and of the red marrow, and might well have become a hæmatologist had not college finance and organisation stolen him from scientific study.

In 1907 Anderson was elected F.R.S., and five years later he was invited to be Master of his College, which had given him a belated Fellowship in 1897. The invitation came as a surprise and was accepted with characteristic diffidence. Apparently he did not see himself fit for this responsibility, but it was soon obvious to everyone else that the choice was happily inspired. His genius for detail, combined with a clear perception of principle, made him peculiarly

SIR HUGH ANDERSON.

suit for such a post. He was a good judge of character; almost too modest by nature, he was free from any vestige of pomposity; and he was courteous, accessible, and sincerely cordial. He has been called the best beloved man of his generation in Cambridge, and when Caius was turned into a staff college during the war many an officer was grateful for the kindness with which Sir Hugh and Lady Anderson made him feel at home.

In the problems of the University after the war Anderson undoubtedly found scope for many of his talents, though the work may not have been what he would have chosen. Conspicuous capacity for business made him an acceptable collaborator in schemes both large and small, and to all of them, once he was convinced of their soundness, he gave an astonishing and self-sacrificing industry. Perhaps the greatest of his tasks was as member of the two university commissions, the first being that appointed in 1919 to consider the needs of Oxford and Cambridge, and the second being the University of Cambridge Statutory Commission which met in 1922. To his friends in Cambridge it seemed that he bore a great part of the weight of the whole proceedings, and he is credited with originating and carrying through many of the constructive proposals, including the provisions relating to the faculty system. On these commissions he was probably the University's most effective representative, and the Council of the Senate recently entrusted him with the delicate negotiations leading up to the Rockefeller Foundation's munificent proposal to give £700,000 to the University towards the cost of the new library and facilities for research. In all these negotiations it was characteristic of him that the financial authorities of the University, the heads of departments concerned, and the representatives of the Foundation should be able to place such confidence in his fairness and judgment that his scheme went through almost exactly as he outlined it.

From Prof. Joseph Barcroft we have received the following appreciation of his work as a physiologist:—

"My personal recollections of Anderson commence in 1893. He was then 'supervisor in physiology' to my own College, which meant, as far as we were concerned, that we went round to his room in Caius nominally for a class once a week. I there learned to know all the qualities which have won the affection, the respect, and the admiration of all who have come in contact with him. The class, perhaps of three, was supposed to last from 8 to 9 P.M.; we rarely came away before 11. During the three hours of its duration Anderson poured out the fruits of a mind entirely selfless, stimulating, rich in imaginative foresight, meticulous as regards correctness of detail, learned and, of course, honest to the very last. Naturally we left with the feeling that physiology was the one thing worth doing, and the life's work of one at least of his pupils was settled there and then.

"In the years which have passed since then Anderson never changed. His energies were devoted to larger objects, but his method remained essentially the same. He seemed to be able to spend endless time and pains over every difficulty, trifling or large, which his friends brought him—and they all did bring their troubles to him. His correspondence was written in his own hand (until shortly before his death); often he wrote the letters two or three times before they pleased him. He drafted reports in the same way. Had he university buildings under consideration his study table would be covered with plans drawn and coloured by himself. He gave himself without stint to every object which was thrust upon him, and the mystery remains unsolved by his friends of how within the 24 hours of a day he could give such detailed attention to so many subjects. Certainly the solution of that mystery did not lie either in superficiality or in failure of appreciation of large issues. Anderson never lost

sight of the wood for the trees, nor in his consideration of the present forgot the possibilities of the future.

"When engaged in physiological research he was always giving of himself to the other workers in the laboratory, his sound critical faculty being helpful to whatever field it was directed. So it remained to the end. Shortly before his death, when he was bearing a weighty burden of affairs, a young worker wrote to him for advice on some matter touching the autonomic system. The next day Anderson made his way to the laboratory in London from which the query came, and devoted at least a couple of hours to the discussion of the problem at issue.

"There is no doubt that the accident of Anderson's diversion to administration (for I think it was largely an accident) was a great loss to science. Against it must be placed the gain which the Universities have reaped from his understanding knowledge of academic needs. Great at administration, he was no mere administrator. In matters financial the heads of departments must, I think, have always felt that in putting their case in Anderson's hands they were placing it where it would receive the greatest consideration, and where every effort would be made to get the most out of the available funds, rather than cut down expenditure irrespective of the loss entailed to academic life. He died in harness, and no better epitaph can be accorded to him than the remark of a friend: 'To have lived without being able to be useful would have been misery to Anderson.'"

At the time of his death Sir Hugh Anderson was a member of the Council of the Royal Society, having previously served in 1917-18. He was also a member of the Medical Research Council, and since 1908 had been chairman of the Syndicate of the Cambridge University Press. He was knighted in 1922, and for many years he had been a governor of Harrow School.

Lady Anderson is the daughter of Surgeon-General F. W. Innes.

FRANK JOSEPH WETHERED, M.D. LOND. AND BRIST., F.R.C.P. LOND.

Dr. F. J. Wethered, whose death at Falmouth on Oct. 28th was announced in our columns last week, had retired to the west country some ten years ago. Although since that time his visits to London were infrequent, he was held in warm remembrance by his colleagues at the hospitals for which he worked and by the staff of this journal, which owed much to his ever-ready help in criticism and comment.

Born at Clifton in 1860, the son of Joseph Wethered, Frank was educated at Clifton College, the Bristol Medical School, where he demonstrated in anatomy, and the London Hospital, from which he qualified M.B. Lond., M.R.C.S. Eng., and L.S.A. in 1885. After holding a house appointment at the London Hospital, he visited some of the more famous continental clinics at Berlin and Vienna before taking his higher medical qualifications and beginning his life-work for the special chest hospitals at Victoria Park, City-road, and Brompton. He was appointed medical registrar and teacher of practical medicine to the

Middlesex Hospital in 1892, holding the former post for three years, and the latter until 1899, when he was appointed assistant physician, after which he had to wait for 14 years before becoming full physician with charge of beds; from this time until his resignation and retirement there was only a period of five years. With his clinical teaching he combined the post of lecturer at the medical school on medical jurisprudence, a subject in which his interest was by no means academic, for he was at pains, as many of his students gratefully remember, to make his lectures something more than a digest of text-book statements. He was also physician to St. Saviour's Hospital. During the greater part of this time, however, he had another outlet for his growing interest in pulmonary diseases, for in 1894 he was appointed assistant physician to the Brompton Hospital, becoming full physician in 1905, a position which he held for nearly 14 years, when he was appointed consulting physician. It was in the field of pulmonary tuberculosis that his advice as a consulting physician was most frequently sought, and his prize essay for the erection of King Edward VII. Sanatorium in 1902 showed how deeply and thoroughly he had thought out the problems of the treatment of tuberculosis, for his essay was in effect a summary of his own experience in the methods of increasing the resistance of the patient, of promoting and encouraging reparative processes, and of developing compensatory growth and function.

"Although Wethered achieved some success in consulting practice, it may be doubted," writes one of his colleagues, "whether this success was commensurate with his undoubted ability and attainments. Of upright, high-principled, and somewhat sensitive nature, the uncertainties of diagnosis and the disappointments of treatment not infrequently oppressed him. Quite early in his professional career he was attracted to the more exact methods of diagnosis, and in 1890 he collaborated with Dr. W. Essex Wynter in the production of a 'Guide to Methods of Clinical Investigation,' one of the early works in English on this subject, showing how clearly the authors foresaw the trend of modern medical practice. The book covered a very wide field, and abounded in practical hints of value to the student, avoiding anything discursive or irrelevant, and the illustrations were a model of excellence for their time. The marriage of his daughter to the late Dr. A. Conyers Inman, clinical pathologist to the Brompton Hospital, later revived Wethered's interest in this subject, and stimulated him to a careful trial of vaccines in the treatment of pulmonary affections. It was the death of Mrs. Inman, his dearly loved only child, as a direct consequence of an infection acquired during war work in hospital, together with his own increasing susceptibility to catarrhal conditions, that determined his retirement from London, although the stress of his work as Captain, R.A.M.C. (T.), at No. 3 London General Hospital, Wandsworth, no doubt contributed to his decision."

Outside his hospital work Dr. Wethered acted as medical adviser to the Equity and Law Life Assurance Society, and examined in medicine for the Royal College of Physicians of London. He was examining physician in London to the Ventnor Consumption Hospital and treasurer to the Medical Defence Union. "All the work Wethered undertook," continues his colleague, "was carried out conscientiously and unstintingly, including arduous work on committees and administrative duties. It was, however, as host in his charmingly furnished house in Harley-street that he was seen at his best. He loved to entertain his friends, colleagues, and hospital assistants. This he did generously and informally, and at these times the happiness of his home life and the devotion of wife and daughter were apparent to all. Wethered will live long in the memory of his friends as a generous, honourable, and loyal man."

After his retirement to Falmouth Dr. Wethered took an active part in the life of the town. He was a consulting physician at the Falmouth Hospital, for a time also at the Royal Cornwall Sailors' Hospital,

and he placed his knowledge and experience at the disposal of the staff of Tehidy Sanatorium. He was a member of the local church council and a regular supporter of the Falmouth Parish Church. His leisure gave him the desired opportunity to indulge in the outdoor sports of which he had always been fond, especially sea-fishing.

Dr. Wethered married, in 1889, Rose, daughter of the late Edward How, who survives him. The interment at St. Marylebone Cemetery on Nov. 1st was attended by many of his old friends and colleagues as a mark of affection and esteem.

SIR GEORGE STEWART ABRAM, M.B. CAMB.,
M.R.C.S. ENG.

THE death of Sir Stewart Abram, which occurred on Oct. 24th at the age of 62 years, robs the Royal Berks Hospital of its senior physician and the town of Reading of one of its most distinguished citizens.

Son of George Abram, of Middle Temple-lane, he was educated at Merchant Taylors' School and at Caius College, Cambridge, where he took a second class in the Natural Science Tripos. From Cambridge he went on to University College Hospital, London, where he obtained the gold medal in midwifery and won distinction in clinical medicine before qualifying as M.B., B.Chir. Camb. in 1891 and taking his conjoint qualification in the same year. He then served as housephysician at his own hospital and assistant house surgeon at the Devon and Exeter Hospital. In 1893 he settled in Reading, where he soon acquired an extensive practice and was appointed to the honorary staff of the Royal Berks Hospital in 1904. His clinical work was marked with a strong vein of

SIR STEWART ABRAM.

Photograph by Drake, Reading.

common sense and a catholicity of interest which is shown in a number of short communications at various times to our own columns. But Abram did not confine his energies to purely professional work. A man of great personal gifts and of indefatigable energy, he was elected shortly after his advent in Reading a member of the town council, serving on it for over 30 years and becoming in 1908 chairman of the health committee, in the work of which he took a leading part; for a considerable period he was also chairman of the Reading Education Committee. In 1919 he was elected an alderman of the borough and was straightway chosen to be Mayor. During his period of office he was mainly responsible for the Reading Historical Pageant, in which he himself was a notable figure. He was also a governor of Reading School, a member of the Court of the University of Reading, an ex-President of the Reading Pathological Society, and a member of numberless charitable, welfare, and athletic committees.

In addition to these varied activities Abram led a busy political life; he was a strong Conservative and

a source of strength to the organisation of the party in the town. For many years he was chairman and, of late, President of the Reading Conservative and Unionist Association. A fluent and graceful speaker, he was in request at both political and non-political gatherings. In January, 1922, his public services were recognised by the conferment of a knighthood. During the war he was a territorial major in the Royal Army Medical Corps and was in command of one of the large war hospitals in Reading. He was interested in all kinds of sport, was an active tennis player, and an amateur actor of some ability.

A few years ago Sir Stewart Abram developed a malignant growth for which he underwent a severe operation. This, on the testimony of a friend and colleague, he faced in the most courageous manner, going about his ordinary work cheerfully until the eve of his admission to the nursing home. After his convalescence he returned to all his activities, in spite of obvious disabilities and to the wonder of all. "Supported," writes W. B. S., "as he had always been, by his heroic wife, he afforded a fine example of pluck in the face of what must have been continual anxiety. As the years went by all hoped that he had been permanently cured, but in the summer of this year lung symptoms commenced, due to a recurrence of the disease. He had always said that he would die in harness, and he continued at work until a week before his death. Abram loved his work and he loved his town. It can truly be said that few men have laboured so unceasingly for the good of their fellows. His untiring energy was amazing. His life's work has indeed been well done."

Owing to his great services to Reading it was recently decided to confer the freedom of the borough on Sir Stewart Abram. It was recognised that the time was short and the presentation was made and the roll signed in his bedroom some seven hours only before he died.

He leaves a widow, a son, and two married daughters.

The photograph of Sir Charles Tomes in our last issue was by Elliott and Fry, Ltd.; that of Mr. Louis Cassidy by Lafayette.

Medical News.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—As the result of the Final Conjoint Examination held from Oct. 1st to 23rd the following candidates were approved in the undermentioned subjects, but are not eligible for diplomas:—

Medicine.—S. S. Ahluwalia, Univ. Coll.; Annie G. Busher, Royal Free; W. J. Cotton and R. Cutler, Guy's; Catherine Day, Royal Free; H. A. Eason, London; Mary G. H. Edwards, St. Mary's; J. A. Fernandez, Univ. Coll.; W. R. Forrester Wood, Cambridge and St. Bart's; Joan Goodger, Charing Cross; Margaret L. Hamburger, Royal Free; E. J. Hamp and J. M. Harker, London; A. H. Hussein, Cairo; A. E. Hutton, Westminster; M. Luckenrain and Dorothy M. Lufkin, Univ. Coll.; R. Machray, Westminster; R. S. Marva, A. Mathews, and M. V. Modi, London; Jocelyn A. M. Moore, Royal Free; W. R. C. Morris, London; B. A. Moss, Guy's; J. E. Myers, London; T. H. Negus, St. Thomas's; J. C. Nicholson, Oxford and St. Bart's; W. G. Oakley, Cambridge and St. Bart's; A. F. Parker, London; W. Pearce, Leeds; G. E. A. Prins, St. Mary's; Marjorie E. Roberts, Royal Free; J. D. Simpson, Cambridge and London; A. E. M. Soliman, Cairo and London; C. M. E. Warner, King's Coll.; S. A. Wickremasinghe, St. Bart's; A. W. Williams, Cambridge and Westminster; J. D. Williams, Cardiff; Beatrice M. Willmott, Cambridge and Birmingham; and Mary Worthington, Royal Free.

Middlesex.—G. G. Allan, Cambridge and Univ. Coll.; K. Alwan-Viechershina, Kiev and Royal Free; H. W. F. Allen, Middlesex; S. Annaswami, Madras; C. Arthur, Cambridge and St. George's; F. L. Ashton, St. Thomas's; Kathleen W. Arlwin-Gibson, Westminster; C. P. Bailey, Cambridge and St. George's; D. P. Ball, Punjab; T. S. Bell, St. Bart's; G. R. Bhatta, Middlesex; W. R. H. Bristow, London; H. J. W. Borch, St. George's; W. R. Bristow, London; M. Bloom, Cardiff; J. J. Boule, London; R. H. A. Boyet, Guy's; Bertha A. Bryant, Royal Free; J. Britton, Berlin and London; T. D. T. Brocklehurst and J. G. Q. Brown, Guy's; V. L. C. Cadogan, Univ.

Coll.; P. Chandra, Punjab and St. George's; H. L. Chopra, Punjab; Mabel J. Cooke, Royal Free; F. S. Cooksey, King's Coll.; C. F. Cosin, Guy's; S. T. Crowther, Cardiff; R. Cutler, Guy's; J. H. Cyriax, Cambridge and St. Thomas's; Catherine Day, Royal Free; E. M. Dimock, Cambridge and Univ. Coll.; Jessie E. Dodds, Sheffield; L. M. Edwards, St. Bart's; A. C. Elkin, Univ. Coll.; R. B. H. Faichney, Liverpool; T. D. Finer, London; A. W. Franklin, Cambridge and St. Bart's; T. Fritz, London; L. Gabbe, Guy's; T. C. R. George, St. Bart's; N. D. Gerrish, Bristol; W. S. Ghai, Charing Cross; P. J. E. Godard, Paris and Lausanne; M. W. Gonin, St. Bart's; A. J. Groenewald, Guy's; E. Grundy, Leeds; L. Grunis, London; A. S. Hall, Cambridge and St. George's; Margaret L. Hamburger, Royal Free; P. N. Hanson, St. Bart's; H. M. Harris, Oxford and London; G. F. Harrison, St. Thomas's; K. W. D. Hartley, St. Bart's; Columba M. D. Heathcote, Charing Cross; F. F. Hellier, Cambridge and Leeds; A. H. Hennessy, Adelaide and London; R. Herring, St. Mary's; R. C. Holderness, Leeds; F. W. Holdsworth, Cambridge and St. George's; G. J. Hollis, Guy's; Ethel E. Hopper, Charing Cross; C. Hortop and A. D. H. Hugo, Guy's; E. F. Hunt, St. George's; R. I. Hyder, London; C. G. Jobbins, Cambridge and St. Thomas's; C. Jones, Leeds; H. W. Jordan, Univ. Coll.; D. W. S. Kaye, King's Coll.; M. S. Khan, Cambridge and Middlesex; T. H. Khan, King's Coll.; R. J. Krogh, Bristol; S. Lal, Lahore; A. J. C. Latchmore, Leeds; C. Leben, Univ. Coll.; A. Liberis, St. Bart's; P. A. T. Lowden, St. Thomas's; J. V. Lucas, Cambridge and Bristol; H. G. McGregor, Guy's; S. I. McMillen, Pennsylvania; F. M. Mallinson, Univ. Coll.; R. S. Mann, Cambridge and Univ. Coll.; F. W. Marshall, King's Coll.; R. S. Marva, Punjab and London; A. Mathews, London; V. L. Misso, Singapore and King's Coll.; S. N. Mistri and W. R. C. Morris, London; Margaret Naylor, Sheffield; A. H. Nelson, Charing Cross; R. J. L. O'Donoghue, Guy's; B. W. Paine, Univ. Coll.; C. T. E. Parsons, St. Bart's; T. B. Pitts, Guy's; R. K. Price, St. Bart's; F. S. C. Pritchard, Guy's; R. Purvis, St. Thomas's; Alison J. Rae, Royal Free; T. V. Rajagopalan, Madras; A. B. Rao, Middlesex; B. V. P. Reddy, London; P. J. Richards, Cambridge and St. Bart's; A. C. Riley, St. Bart's; Marjorie E. Roberts, Royal Free; Ivy H. V. Rowlands, Liverpool; C. R. Salkeld, Oxford and St. Thomas's; R. M. Sargent, Univ. Coll.; T. L. Scott, St. Mary's; S. Segalov, St. Bart's; S. R. Selby-Green, Westminster; W. H. H. Sersinghe, Middlesex; V. Seshagiri-Rao, Madras; E. M. Sharples, St. Bart's; H. J. Shorvon, St. Thomas's; A. D. Skyrme, Cambridge and London; A. M. Soliman, Cairo and London; H. Stark, St. Bart's; Ada M. W. Stewart, Liverpool and Univ. Coll.; G. D. Stilwell, St. Thomas's; L. Sumitra, St. Mary's; E. C. Surden, Cambridge and St. Bart's; B. L. Taneja, Lahore and Guy's; H. Taylor, Cambridge and St. Bart's; V. C. Thompson and C. R. Todd, St. Bart's; Decima M. Tracey, Royal Free; A. E. Treweek, Guy's; D. P. Turner, King's Coll.; G. E. M. Turner, Middlesex; G. V. Vashnavi, Punjab; J. J. van Niekerk, Guy's; Frances J. Vinter, Royal Free; W. E. Wainman, Leeds; W. J. Walter, Oxford and St. Bart's; V. W. L. Wells, Guy's; S. A. Wickremasinghe, Ceylon and St. Bart's; S. J. Wheeler, Guy's; R. P. White, Cambridge and St. Bart's; D. C. Williams, Cardiff; J. O. Williams, St. Bart's; Sibyl O. Williams, Calcutta and Royal Free; E. R. Willis, London; Beatrice M. Willmott, Cambridge and Birmingham; B. Wright, Cambridge and St. Bart's; Winifred M. Wright, Royal Free; P. Yarmarko and D. J. Young, Middlesex; and R. H. Young, Cambridge and St. Thomas's.

Surgery.—W. Adder, Manchester; C. L. Ahluwalia, Charing Cross; C. Arthur, St. George's; M. W. Atkinson, Middlesex; R. C. Bennett, St. Bart's; A. D. D. Broughton, London; G. H. Buck, Oxford and Westminster; G. C. Cochrane, London; J. E. Curnock, Charing Cross; E. M. Dimock, Univ. Coll.; J. A. Eddy, Middlesex; M. A. A. El Gammal, Cairo; A. C. Elkin, Univ. Coll.; T. C. J. Evans, St. Mary's; A. D. Everett, St. Bart's; R. B. H. Faichney, Liverpool; E. Foster, Cardiff; P. J. E. Godard, Paris and Lausanne; M. W. Gonin, St. Bart's; A. J. Groenewald, Guy's; R. G. Gwynne, Adelaide and London; A. S. Hall, St. George's; H. M. Harris, Oxford and London; G. F. Harrison, St. Thomas's; Dorothy C. Hay, King's Coll.; W. Heath, St. Bart's; C. E. Holden, Cambridge and St. Bart's; F. W. Holdsworth, Cambridge and St. George's; G. J. Hollis, Guy's; R. G. S. Howe, Univ. Coll.; A. E. Hutton, Westminster; R. J. Hyder, London; D. E. Hyman, Manchester; C. G. Jobbins and W. H. P. Jonas, St. Thomas's; C. Jones, Leeds; H. W. Jordan and C. Leben, Univ. Coll.; L. C. Lodge, Middlesex; R. Machray, Westminster; F. W. Marshall, King's Coll.; R. A. Maynard, Cambridge and St. Thomas's; J. C. Nicholson, Oxford and St. Bart's; P. L. Nirula, Punjab; P. Parakutty-Ammal, Royal Free; E. R. G. Paise, London; P. Pomarantz, St. Bart's; R. Purvis, St. Thomas's; Florence Ram, Cambridge and Sheffield; A. B. Rao, Middlesex; A. C. Riley, St. Bart's; E. B. Rogers, Guy's; B. Rothery, St. George's; A. S. D. Russell, St. Thomas's; T. L. Scott, St. Mary's; J. D. Simpson and B. Singer, London; E. Sladen and C. E. Sooden, Middlesex; B. Stanley, Univ. Coll.; E. T. W. Starke, St. Mary's; E. C. Surden, Cambridge and St. Bart's; Bertha M. Upton-Jones, Royal Free; E. Vitenson, Guy's; W. E. Wainman, Leeds; R. P. White and A. G. Williams, St. Bart's; Kathleen Wilson, King's Coll.; and W. R. Winterton and M. R. Zada, Middlesex.

Pathology.—A. D. Everett, St. Bart's; A. Gilpin, King's Coll.; E. Grundy, Leeds; J. M. Harker, London; R. C.

Holderness, Leeds: Geraldine J. G. Hayes, Manchester; D. W. S. Kaye, King's Coll.; S. D. McClean, Guy's; J. R. Owen, Birmingham; R. A. G. Rice, St. Bart.'s; T. S. Rodgers, Westminster; C. Skinner, Guy's; A. R. Smith, St. Thomas's; I. Taylor, King's Coll.; and A. Wiseman, Guy's.

UNIVERSITY OF OXFORD.—The following scholarships have been awarded:—Theodore Williams Scholarship in Physiology: Robert A. Beaver. Theodore Williams Scholarship in Anatomy: Renatus Kempthorne and Aldwyn B. Stokes, B.A. (equal). Theodore Williams Scholarship in Pathology: Frank Hawking. Radcliffe Scholarship in Pharmacology: Hedley John Barnard Atkins and John Henderson Hunt (equal).

UNIVERSITY OF CAMBRIDGE.—It is proposed to confer the honorary degree of Master of Arts upon Mr. W. H. Bowen, F.R.C.S., surgeon to Addenbrooke's Hospital.

UNIVERSITY OF EDINBURGH.—Sir Leybourne Davidson has given £5000 to found and endow a Fellowship in Bacteriology and Immunology in the University.

ROYAL SOCIETY OF ARTS.—The Cantor lecture on Biology and Refrigeration will be delivered by Mr. Franklin Kidd, D.Sc., on Nov. 12th, at 8 P.M., at the house of the Society at John-street, Adelphi, London, W.C.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES.—Dr. C. S. Myers, F.R.S., will take the chair at a lecture on Race and Civilisation, to be given by Mr. Morris Ginsberg at 8.15 P.M., on Tuesday, Nov. 13th, at the Royal Society of Arts, 18, John-street, Adelphi, W.C.

MEDICO-LEGAL SOCIETY.—A meeting will be held at 11, Chandos-street, Cavendish-square, London, W., on Nov. 22nd, at 8.30 P.M., when a paper will be read by Dr. L. A. Weatherly on Juvenile Psychologic Delinquencies—their Origin and Treatment, which will be followed by a discussion.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—A meeting of this Society will be held at the Miller General Hospital, Greenwich, to-day, Friday, Nov. 9th, at 8.45 p.m., when Mr. C. A. Joll, the President, will take the chair, and Dr. J. A. Ryle will give an address on Some Symptoms and Consequences of Arterial Disease.

LONDON CLINIC FOR RHEUMATISM.—Sir Otto Beit, who in May last gave £10,000 in answer to the British Red Cross Society's appeal for £40,000 to establish a clinic in London for the treatment and study of rheumatic diseases, has now sent a further donation of £3474 18s. 9d., being the amount required to complete the sum asked for.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The annual dinner of this society will be held at the Piccadilly Hotel, W., on Thursday, Nov. 15th, at 7.30 P.M. (Reception at 7.10 P.M.) Ladies are invited, and members, or candidates nominated for election, are asked to give early notice to the executive secretary of their intention to be present, with the names of their guests.

ABERDEEN UNIVERSITY CLUB, LONDON.—This club will hold its eightieth half-yearly dinner at the Trocadero Restaurant on Nov. 22nd, with Lord Meston, Chancellor of the University, in the chair, and with the Earl of Birkenhead, Rector of the University, as principal guest. Application for tickets to the secretary, 9, Addison-gardens, Kensington, W. 14.

COLLEGE OF NURSING.—Miss Cox-Davies, C.B.E., has been appointed president of the College in succession to Miss Gill, who has retired owing to ill-health. At one time matron of the Royal Free Hospital, London, Miss Cox-Davies was a principal matron of the Territorial Army Nursing Service during the war, and was decorated with the Royal Red Cross and bar. She is a member of the General Nursing Council.

DONATIONS AND BEQUESTS.—Under the will of the late Mr. E. Freamer, of Windsor, who left the residue of his estate to King Edward VII. Hospital, that institution will receive about £10,000.—Mr. William Greenwood, of Lytham, Lancs, left £1000 to the Rochdale Infirmary and £500 to the Cottage Hospital, Lytham.—The Invalid Children's Aid Association of Manchester and Salford has received an anonymous gift of £1000.—Mr. Maximilian Maurice Samuel, of Willesden-lane, London, on his wife's decease, left £1000 to the Willesden General Infirmary.—Mr. Levy, chairman of the Ardath Tobacco Co., Ltd., has given £2000 to the New Bethlem Hospital Building Fund.

ROYAL SOCIETY.—At the anniversary meeting on Nov. 30th the President and Council will recommend that Dr. H. H. Dale be re-elected as one of the society's two secretaries, whilst Dr. Charles Bolton, Dr. C. G. Douglas, Sir Frederick Hopkins, Prof. J. C. G. Ledingham, and Prof. G. Elliot Smith are among the Fellows nominated to the Council.

THE IRIS FOX MEMORIAL.—The Committee of this Fund announce that a total of £355 has been collected, and that it is proposed to utilise the money for a pathological library at the Royal Free Hospital to be named the Iris Fox Library.

Dr. Thomas Goodall Nasmyth has been appointed a Deputy Lieutenant of Edinburgh.

Dr. Herbert Gordon Thompson has resigned his post in charge of the Church Missionary Society's Hospital at Hangchow, China, on being appointed to the Chair of Surgery at the Henry Lester Institute, Shanghai.

UNIVERSITY OF LONDON MEDICAL GRADUATES' SOCIETY.—The autumn dinner of this society was held at the Langham Hotel, London, on Oct. 31st, with the President, Sir StClair Thomson, in the chair, and Dr. M. Hajek, Professor of Rhino-Laryngology in the University of Vienna, and Dr. Waldapfel, his assistant, as the guests of honour. After referring to the increasing membership of the society, which now includes 200 life members, he pointed out that the medical graduates of the University numbered upwards of 4500, and expressed a hope that a larger proportion would join as time went on. He expressed the society's welcome to Prof. Hajek, who responded. Mr. W. McAdam Eccles recounted the success achieved in the Birmingham area through the energy and initiative of Prof. W. Billington, in consequence of which the first extra-metropolitan dinner of the society will be held in Birmingham on Nov. 23rd at 7.30 P.M., in the Queen's Hotel, with Sir StClair Thomson in the chair. Sir Holburt Waring then described some of the latest developments with regard to the Bloomsbury site. He stated that 11 acres had been acquired for £535,000, consisting of four blocks through which ran two roads crosswise. At present the University was receiving £14,000 per annum in rentals from these buildings. Legislation had had to be sought by which the University would be enabled to close these two intersecting roads, the roads to the south and east sides of the area being widened as a compensatory measure. The necessary powers had been successfully achieved, with the help of the London County Council, and the University was now able to go ahead with the development scheme. The authorities were now trying to decide what institutions, colleges, and special departments should be erected upon the site. When this had been decided, after consultation with the various bodies concerned, designs for the whole plan of the area would be invited from leading architectural authorities. The purchase of the site had been finally accomplished by arrangement with the Treasury, the Rockefeller Institute, and the University trustees.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
MONDAY, Nov. 12th.—5 P.M., WAR. Paper: Major W. D. Keyworth, I.M.S.: Severe Malaria among British Troops in the East African Campaign. (Communicated by Major Herriek, I.M.S.)
TUESDAY.—5 P.M., THERAPEUTICS AND TROPICAL DISEASES. Joint discussion on the Special Uses of Antimony. Opener: Dr. J. B. Christopherson. Other Speakers: Prof. A. J. Gunn, Sir Leonard Rogers, and others.
 8.30 P.M., PSYCHIATRY. Presidential Address: Sir Maurice Craig: A Survey of Some Conditions Conducive to Mental Disturbance, with Suggestions as to Their Treatment.
WEDNESDAY.—5.30 P.M., SURGERY: SUBSECTION OF PROCTOLOGY. Discussion on Urinary Infections after Excision of the Rectum; Their Cause and Prevention. To be opened by Dr. Cuthbert Dukes. Demonstration of pathological specimens. 8.15 P.M., ELECTRO-THERAPEUTICS. Mackenzie Davidson Memorial Lecture: Prof. W. L. Bragg: X Ray Optics (Illustrated by experiments). (Note.—There will be no meeting of the Section of Electro-Therapeutics on Friday, Nov. 16th.)

THURSDAY.—5 P.M., DERMATOLOGY. (Cases at 4 P.M.) Cases: Dr. H. C. Semon: Keratoderma Punctata. Other cases will be shown. Annual Dinner of the Society: May Fair Hotel, W. 1, 7.30 for 8 P.M.

FRIDAY.—8 P.M., ONSTETRICS. Short Communication: Dr. J. D. Barris and Dr. Wilfred Shaw: Rhabdomyosarcoma of the Ovaries. Papers: Prof. Donald and Prof. Fletcher Shaw: Age-incidence in Carcinoma of the Body of the Uterus. Dr. James Young (Edinburgh): The Prognosis and Treatment of Late Pregnancy Toxæmia.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Nov. 12th.—8.30 P.M., discussion on the Medical-Legal Aspects of Fractures, to be introduced by Prof. E. Hey Groves and Dr. James Neal.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

THURSDAY, Nov. 15th.—8.15 P.M. (at the London School of Hygiene and Tropical Medicine, Endsleigh-gardens, Euston-road, W.C.). Laboratory Meeting. Demonstrations by Major H. C. Brown and Dr. W. T. C. Broom: Dr. P. A. Buxton: Dr. L. J. Davis: Mr. B. Joblin: Dr. Salisbury Sharpe: Miss E. K. Sikes: Dr. A. C. Stevenson: Dr. C. M. Wenyon and Dr. E. Hindle: Dr. V. B. Wigglesworth, and Prof. Warrington Yorke. A cinematograph film will also be shown entitled Scenes in the Kala-azar Endemic Areas in Bengal, by Dr. L. E. Napier, of Calcutta.

BIOCHEMICAL SOCIETY.

FRIDAY, Nov. 16th.—5 P.M. (in St. Thomas's Hospital Medical School). Communications:—V. B. Reader: A Third Factor Present in Marmite. Necessary for the Nutrition of the Rat. H. J. Holman and S. B. Schryver: The Separation of the Basic Products of the Hydrolysis of Proteins. J. R. Marrack: Ketosis in Sea-sickness. L. J. Harris and T. Moore: Hyper-vitaminosis. M. G. Eggleton and P. Eggleton: A Method of Estimating Phosphagen and other Phosphorus Compounds in Voluntary Muscle. W. J. N. Burch: A Synthesis of Hydroxyglutamic Acid. W. J. N. Burch and R. H. A. Plimmer: Esters of Phosphoric Acid. J. Lowndes and R. H. A. Plimmer: Bromination of Histidine. R. H. A. Plimmer, W. H. Raymond, and J. Lowndes: Comparative Vitamin B Values of Foodstuffs. H. Allen, F. Dickens, E. C. Dodds, and F. C. Howitt: A Study of the Estrus-producing Hormone, with Special Reference to its Preparation and Standardisation in a Water-soluble Form.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Nov. 12th.—10 A.M., Dr. Burnford: General Practitioner. 11 A.M., Mr. Tyrell: General Practitioner. 2 P.M., Mr. Simmonds: Surgery.

TUESDAY.—11 A.M., Mr. Endea (demonstration). 2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose and Ear Department.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Ironside: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department. 4.30 P.M., Special lecture: Mr. Vlasto: Hoarseness.

SATURDAY.—9 A.M., Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.

Daily 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anæsthetic Course.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Nov. 12th.—2.30 to 5 P.M.: Medical, Surgical, and Gynaecological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Nov. 12th, to SATURDAY, Nov. 17th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Lectures by Dr. H. C. Semon: Some Basic Remedies in Diseases of the Skin, on Mon., at 5 P.M.; WILKINS MUSEUM OF MEDICAL SCIENCE, 53, Gordon-street, W.C. Wed., at 4 P.M., demonstration by Colonel A. W. Harrison: Syphilis Now and Twenty Years Ago.—CENTRAL LONDON OPHTHALMIC HOSPITAL, Judd-street, W.C. Mon., at 4.30 P.M.,

clinical demonstration by Mr. Williamson-Noble. There are no fees for the above.—SOUTH LONDON HOSPITAL FOR WOMEN, 103, South Side, Clapham Common, S.W. Fri., at 2 P.M., clinical demonstration by Miss Davies-Colley and her colleagues. This demonstration is free to women graduates only.—ROYAL WATERLOO HOSPITAL FOR WOMEN AND CHILDREN, Waterloo-road, S.E. Special post-graduate course in medicine, surgery, and gynaecology.—ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, Broad-street, Holborn, W.C. Special course in ophthalmology.—ST. MARK'S HOSPITAL, City-road, E.C. One week's special course. Further information from the Secretary.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Nov. 15th.—4 P.M., Dr. Frew: Enuresis.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Nov. 16th.—4 P.M., Diseases of the Maxillary Antrum.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Nov. 13th.—3.15 P.M. (at the Royal Chest Hospital), Dr. P. Kerley: The X Ray Diagnosis of Pulmonary Tuberculosis.

ST. PAUL'S HOSPITAL POST-GRADUATE COURSE, Endell-street, W.C.

WEDNESDAY, Nov. 14th.—4.30 P.M., Mr. H. P. Winsbury White: Stone in the Upper Urinary Tract.

UNIVERSITY COLLEGE, Gower-street, W.C.

MONDAY, Nov. 12th.—5 P.M., Prof. E. B. Verney: Urinary Secretion. (Fifth lecture.)

WEDNESDAY.—5.30 P.M., Dr. J. Owens, A.M.I.C.E.: Smoke Pollution of the Air and Public Health. (Last lecture.)

FRIDAY.—5 P.M., Prof. J. C. Drummond: Recent Work on Vitamins. (Last lecture.)

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

WEDNESDAY, Nov. 14th.—4 P.M., Dr. R. H. B. Adamson: The Health of Women and Girls in Relation to Industry.

CHADWICK PUBLIC LECTURES.

MONDAY, Nov. 12th.—8 P.M. (at Royal Institution of Civil Engineers, Great George-street, Westminster), Mr. H. E. Stilgoe, M.Inst.C.E.: Some Aspects of the London Water-supply.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Nov. 13th.—5 P.M., Dr. Wilfrid Fox: Nævi.

THURSDAY.—5 P.M., Dr. I. Muende: Pathology Demonstration.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

FRIDAY, Nov. 16th.—3.30 P.M., Mr. Mouat: Surgical Cases.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Nov. 13th.—4.15 P.M., Dr. W. Dyson: Demonstration of Dermatological Cases.

FRIDAY.—4.15 P.M., Dr. W. G. Thomson: Certification in Lunacy.

ANCOATS HOSPITAL POST-GRADUATE LECTURES, Mill-street, Manchester.

THURSDAY, Nov. 15th.—3.45 P.M., Dr. Renshaw: Urine—Laboratory Aids to Diagnosis.

Appointments.

FALLON, M. F., M.B., B.Ch. Belf., has been appointed Assistant Medical Officer of Health for Bury, Lancashire.

Certifying Surgeons under the Factory and Workshop Acts: **DAVIES, A. J. M., L.M.S.S.A.** (Corris, Merioneth); **HERINGTON, C. E. E., M.B., B.S. Lond., D.P.H. (Erith, Kent.)**; and **WYARD, A. T., L.R.C.P. Lond., M.R.C.S. (Pangbourne, Berks).**

Vacancies.

For further information refer to the advertisement columns.

Birmingham and Midland Homœopathic Hospital, Easy-road, H.S. £150.

Birmingham, Midland Ear and Throat Hospital.—Asst. Surg. O. Also Second H.S. £200 and £150 respectively.

Birmingham, Queen's Hospital.—Asst. Ophth. Surg. £50.

Cambridge, Papworth Village Settlement.—H.P. At rate of £100.

Cardiff, King Edward VII. Welsh National Memorial Association.—Asst. Tuberc. P. £600. Also Third Asst. Res. M.O. to N. Wales Sanatorium, Manawgan, £200.

Chesler, Royal Infirmary.—Three H.S.'s. Each £120.

City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—Res. M.O. £250. Also H.P. At rate of £100.

Croydon, General Hospital.—Res. M.O. £200.

Dreadnought Hospital, Greenwich.—Med. Supt. £300.

Dublin, Royal City of Dublin Hospital, Upper Baggot-street.—Visiting Gynaecologist.

Dudley, Guest Hospital and Eye Infirmary.—H.S. Also Asst. H.S. £175 and £150 respectively.

East London Hospital for Children, &c., Shadwell, E.—Asst. Surg. Elizabeth Garrett Anderson Hospital, Euston-road.—Clin. Assts. Exeter City.—Asst. M.O.H., &c. £600.

Exeter, Wonford House.—Jun. Asst. M.O. £300.

Frimley, Hospital for Consumption Sanatorium.—Sen. and Jun. H.P.'s. At rate of £150 and £100 respectively.

Halifax County Borough.—M.O.H. £1000.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—Hon. Ophth. Surg.

Harefield, Middlesex, County Sanatorium.—Third Asst. Res. M.O. £100.

Hospital for Sick Children, Great Ormond-street, W.C.—H.P. and H.S. Each at rate of £100. Also Res. M.O. for Country Branch Hospital, Tadworth, Surrey. At rate of £250.

Hospital for Women, Soho-square, W.—Pathologist and Registrar. £100.

Huddersfield Royal Infirmary.—H.S. £150.

Hull, Royal Infirmary.—Second H.S. At rate of £150.

King's College Hospital, Denmark Hill, S.E.—Sister-Matron. Also Supernumerary Jun. Ophth. Surg.

L.C.C. Mental Hospitals Service.—Eighth Asst. M.O. £300.

St. James's Hospital.—H.P. and S. £200.

Stepney Green, E.—Hon. Asst. Phys. Memorial Jewish Hospital, Cheetham.—H.S. £125.

Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Hon. Dental Surg.

Nottinghamshire County Council.—Tuberculosis Officer. £750.

Peterborough and District Memorial Hospital.—Hon. Asst. Surg. Pontypriid, Llanynypia, Hospital.—Res. Asst. M.O. £300.

Portsmouth, Royal Portsmouth Hospital.—Sen. H.S. At rate of £200.

Reading, Royal Berkshire Hospital.—Pathologist, &c. £750. Also Third H.S. and Res. Anaesthetist. At rate of £150.

Royal College of Surgeons of England.—Election to Court of Examiners.

Royal Free Hospital, Gray's Inn-road, W.C.—Res. H.S.'s and Res. H.P.'s. Each £150. Surg. Reg. £200. Gyn. Reg. and Med. Reg. Each £100.

Royal Northern Hospital, Holloway, N.—Out-patient M.O. Also H.S. At rate of £125 and £70 respectively.

St. Marylebone Hospital, Ladbroke-grove, W.—Third Asst. M.O. £300.

St. Ma Sheffield.—Res. M.O. £150.

Sheffield.—Pathologist, £500.

Sheffield.—Pathologist, &c. £500.

South.—Pathologist, &c. £500.

Clin. Asst. 1 guinea per attendance.

Swansea Hospital.—H.S. £150.

Walsall General Hospital.—H.S. At rate of £125.

Warrington Infirmary and Dispensary.—Sen. H.S. £300.

West London Hospital, Hammersmith-road, W.—H.P., H.S. Also Aural and Ophth. H.S. Each at rate of £100.

Winchester, Royal Hampshire County Hospital.—H.P. £150.

Worcestershire County Council.—Asst. County M.O. £600.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Carnwath (Lanarkshire) and Bruton (Somerset).

Notes, Comments, and Abstracts.

A BROADCAST TALK ON THE ULTRA-VIOLET RAYS.

Given from the London Wireless Station on Nov. 7th by
SIDNEY RUSS, D.Sc.,

PROFESSOR OF PHYSICS, MIDDLESEX HOSPITAL MEDICAL SCHOOL.

ULTRA-VIOLET rays were discovered as long ago as 1800, but it is only comparatively recently that people other than scientists have taken much interest in them. But to get back to the beginning of the subject one has to go back as far as 1666, when Isaac Newton made his famous experiment. He let a beam of sunlight pass through a glass prism and found that this beam was apparently split into a lot of different rays, which are now known as the spectral colours.

Newton's experiment may be arranged so that the rays emerging from the prism fall on a white screen and the band of different coloured lights, ranging from red at one end to violet at the other, can be carefully examined. Between the red and violet are the bands of orange, yellow, green, blue, and indigo.

There is no definite point where the violet light stops, as some people can see a little further than others in the region of light, but no one can see any colour beyond a certain limit, and this is where the ultra-violet rays begin.

These rays are normally present in sunlight, but, as they are invisible, Newton did not detect them. Although they cannot be seen, they have a profound effect on many things; photographic plates, for instance, are much more sensitive to ultra-violet rays than to ordinary light; in fact, the discovery of ultra-violet rays was due to their chemical action. These changes are not only of great interest and importance in the study of chemistry, but also in agriculture and medicine.

The use of ultra-violet rays in medicine is often called actinotherapy, and, although this is a new name, it is not entirely a new method of treatment; in fact, it is one of the oldest. There is historical evidence that 3000 years ago the healing powers of sunlight were appreciated to some extent, and there are definite records that the ancient Egyptians, Greeks, and Romans used it as a curative agent.

Ultra-violet rays, which are one of the invisible parts of sunlight, are showered out by the sun and reach the earth in the same way as light does.

Although there is not much apparent difference on a sunny day between the sunlight in a valley and on a mountain top 10,000 feet up, there is a great difference in the amount of ultra-violet rays reaching the two places, because 10,000 feet of air will absorb quite a large amount of these rays, especially if the air is dusty. In this way sunlight in large smoky cities is robbed of nearly all its ultra-violet. It is chiefly these rays which tan the skin, and during the coal strike in 1921, when very little fuel was burnt in open hearths, there were unmistakable signs of tanned faces among the London population, a phenomenon probably not witnessed for hundreds of years.

The ordinary artificial sources of light, either candle, lamp, gas burner, or electric bulb, do not give out much ultra-violet radiation. The best way to produce these rays artificially in any quantity is to use some sort of arc lamp, either one open to the air, like the ordinary carbon arcs used for street lighting, or a closed mercury-vapour lamp. The ultra-violet rays can be separated from light by the simple process of filtering; the screen or filter used is a special kind of glass, invented by Prof. Wood, of America, which lets through the invisible rays but stops the visible ones. This glass makes it possible for us to see what things look like with ultra-violet rays only shining on them, if it is permissible to use the word "shining." Though the rays are quite invisible they can make things light up when they fall on them, giving them a rather weird and wonderful appearance.

In the Natural Science Museum at South Kensington an exhibit has been installed showing the appearance of a number of minerals in ordinary light and under ultra-violet rays: the difference revealed is amazing. Many insects, too, show similar contrasts. Our sense of wonder is rather quickened at the thought that the dim lit night hours (which are not devoid of ultra-violet rays) may be for the more seeing world not darkness at all, but simply a change of setting, where objects inconspicuous in blazing sunlight stand out conspicuously as they transform into light the ultra-violet rays which fall on them.

If people are examined under ultra-violet rays they bear very little resemblance to their normal daylight appearance; their faces look rather like alabaster with bright

Births, Marriages, and Deaths.

BIRTHS.

BROWNE.—On Nov. 1st, at Welbeck-street, W., the wife of Denis Browne, F.R.C.S., of a daughter.

NEWMARCH.—On Nov. 1st, to Gwendoline, the wife of Dr. J. H. Newmarch, of Evelyn-gardens, S.W., of a daughter.

SPERO.—On Nov. 2nd, at Lancaster Gate-terrace, W., the wife of Dr. G. E. Spero, of a daughter.

MARRIAGES.

COLLEN—COOPER.—On Oct. 31st, at Brighton, Edward Victor Collen, B.A., M.D., to Celia Phyllis, younger daughter of the late Sir Pope Cooper, K.C.M.G., Chief Justice of Queensland.

YOUNG—BUCKLE.—On Oct. 27th, at Norbiton, Surrey, Matthew Young, M.D., to Mary Gladys Buckle.

DEATHS.

BROADBENT.—On Nov. 2nd, suddenly, at Cambridge, Reginald Broadbent, M.D., of West Parade, Bexhill.

MOORHEAD.—On Oct. 28th, at Harrow, James Herbert Moorhead, M.D., of Sunnyside, Raglan-road, Smethwick, aged 55 years.

PAULING.—On Oct. 30th, at Ashley-gardens, S.W., William Tennant Pauling, M.R.C.S., L.R.C.P., aged 61.

SELBY.—On Oct. 31st, at 16, Sunderland-terrace, W. 2, Peggy, the loving and much loved only child of the late Major R. Selby, R.A.M.C., and Mrs. Selby, after a long and painful illness borne with exemplary patience. Funeral at Lansdowne, Bath. We asked life and Thou gavest it to her.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

spots here and there, their hair loses all the lustre and looks something like straw, their teeth are glaringly white unless they are artificial, in which case they appear quite black. The appearance of the eyes is curiously striking, for the ordinary colouring hardly shows, but the clear covering of the eye and lens are seen to glow with a pale lavender colour which gives a weird appearance. The portrait outlined is not a very becoming one but it is full of interest, showing as it does the many different ways in which the tissues of the body respond or react to these rays.

The whole of vegetable life is directly or indirectly dependent on sunlight; and growth, which is a series of such very complicated processes, is one of the problems which chemists at the present time are trying to unravel. Prof. Baly, of Liverpool University, has found that sugar can be formed from comparatively simple compounds by the action of ultra-violet rays. Some of the vitamins about which so much is heard to-day, and which appear to be essential for our well-being, are also affected or produced by these rays. A deficiency of one of these vitamins in the diet of children gives rise to rickets. A study of the disease in the years following the war showed that, if children were given suitable doses of ultra-violet rays, they did not develop rickets even when they were fed on a diet so deficient that they would ordinarily be pretty sure to get the disease. The conclusion was naturally drawn that the vitamin was somehow produced by the rays acting on the body, although this seemed hard to believe, as ultra-violet rays scarcely penetrate through the skin. So the only possible inference seemed that the vitamin was produced by the action of the rays on something in the skin, which was then set free in the body, and so affected the general well-being of the child. This view is now generally held, and it is no exaggeration to say that the children are literally nourished by sunlight and that ultra-violet rays play some part in the process.

These rays began to be used medically in 1893 by Finsen at Copenhagen, and the splendid institute there which bears his name is a tribute to the memory of a man who died of tuberculosis, yet was able to cure the disease in certain forms in others.

In Alpine sanatoria, where patients get the benefits of the pure bracing mountain air, Finsen's ultra-violet methods are still used with some modifications. The whole body is gradually exposed to the sun's rays until the skin has become quite tanned by the exposures. In England, too, at Alton and Hayling Island, at the institutions begun by the late Sir William Treloar and organised by Sir Henry Gauvain, wonderful examples of the benefits which can be derived from life in sunshine and the open air may be seen. For many months in the year when there is so little sunshine it is necessary to use artificial sources of light and ultra-violet rays for the treatment of disease, and gradually the term "artificial sunlight" has crept into use.

The suggestion has been made in various quarters that normal healthy people should have doses of this so-called "artificial sunlight" in the dull months of the year. Why should not it be installed in our houses so that we may enjoy something like sunshine when we cannot have the real thing? Judging by the statements made during the last five years this must have been done to some extent, and many people are using these rays at their own discretion. It may be useful to remind them that these lamps are not really artificial producers of true sunlight, and that they give out rays which may turn out to be harmful in their action in some ways instead of entirely beneficial as is now generally supposed.

At the present time our knowledge of the action of ultra-violet rays is very incomplete, and it seems a very unwise policy for people to use them, either upon themselves or their children, except under proper medical supervision. Otherwise we are faced with the fact that an experiment on a very big scale is being undertaken without any direct medical control.

Extensive use of the valuable properties of these rays in the treatment of disease is being made by medical experts, but the normally healthy individual is probably better off if he enjoys real sunshine when he can get it than if he experiments with the artificial variety.

ROYAL ALEXANDRA HOSPITAL FOR SICK CHILDREN.

On Oct. 31st, the ultra-violet light department and new operating theatre of this hospital at Brighton were inaugurated, an event which marked the completion of the new wing which was formally opened in May last by the Duke and Duchess of York. Originally, the hospital possessed only one ultra-violet lamp, but it has now five; and together the institution may be said to have been brought thoroughly up to date. The cost of the new wing has been about £12,000.

SELECTION OF TRAM AND 'BUS DRIVERS.

THE industrial psychologist now has his part to play in the prevention of traffic accidents. The Director of the Laboratory of Experimental Psychology at the Practical School of Higher Studies, attached to the Sorbonne, Paris, has recently published the results of several years' study of the psycho-physiological selection of Paris tram and 'bus drivers.¹ In 1921 he was appointed by the Paris General Transport Company (which runs all the 'buses, trams, and Seine steamers) to examine and select all their personnel, numbering about 30,000. Before the laboratory was established, 20 per cent. of the drivers were found to be unsuitable either during or after their apprenticeship. Since the tests have been made, the proportion of failures has fallen to 3.4 per cent. The number of accidents to selected drivers during their first year's service has been 16.5 per cent. less than those happening to unselected drivers.

Candidates are first examined medically and then psycho-technically. The various apparatus and processes employed cannot be described here, but the technician will find them in Mr. Laby's book. One of the most important tests, named the "diffused attention" test, aims at measuring the candidate's ability to take quick decisions amid the sights and sounds of a crowded street. Another measures the "emotivity" of the subject, in view of the fact that these accidents are often caused by nervous injuries due to or connected with some previous accident. It seems but a short step from the tram or 'bus driver to the chauffeur, amateur or professional. We know of no country yet where a psychological examination is made of would-be chauffeurs, though the majority oblige them to pass a mechanical test before they receive their licence. The increase in the number of street accidents in London, Paris, and New York of recent years has been appalling. If the industrial psychologist can reduce such accidents, his help should be welcomed both by chauffeurs and pedestrians.

A HALFPENNY NEWSPAPER FOR DOCTORS.

THE *Siccle Médical*,² which is "exclusively reserved to the corps médical," has been on sale regularly every fortnight in Paris during the last two years for 20 centimes, rather less than one halfpenny. It is safe to say that such a venture could have succeeded only under powerful auspices, and inquiry reveals that the *Matin* is the father of this promising child, who has embraced the medical profession from his cradle. In size and appearance the *Siccle Médical* is not attractive: it contains half a dozen sheets of cheap paper, printed with evil-smelling ink, and dotted about with unflattering portraits of medical experts. Its contents, however, are distinctly valuable. It really is a newspaper, not a medical journal, and almost every item would be acknowledged by a professional journalist to have "news value" for its readers. The front page is mainly given over to accounts of medical and public health congresses. Other contributions are reports of scientific societies, new items relating to medicine from the provinces and abroad, a medical bibliography, a dental page, a literary page, a wireless column, and a page for the medical motorist. A formal notice is published in each number that the *Siccle Médical* accepts no advertisements of pharmaceutical specialties addressed directly to the public. It reserves the right of refusing any advertisement, the text or object of which appears doubtful to it, or which does not live up to the standard of its readers. The majority of the advertisements printed relate to objects of daily use, but some advertise laboratory preparations and surgical supplies.

A POCKET MEDICAL DICTIONARY.

THE pocket edition of Gould's Medical Dictionary has reached its ninth issue (London: H. K. Lewis and Co., Ltd. Price 10s.). This little book, which may be carried comfortably in the coat pocket, measures 6½ in. by 3½ in., and in its unnumbered pages contains over 40,000 words used in medicine and the collateral sciences, with the proper pronunciation and a short definition. Some months of use are necessary to test the qualities of such a book, and as a French writer once remarked: "Le meilleur dictionnaire est celui qui est le moins mauvais." The errors are in fact very few indeed, but V stands for Vanadium and not Vanadium, while a Megohm is a million ohms and not one-millionth part of an ohm. It is almost too late to say that vitamins are "unknown substances": quite a lot is now known about them. We are glad to see "Apple Head" as a term for the broad, thick skull of dwarfs: even some big dictionaries do not give this. "Pocket Gould" in its revised form is a safe and useful companion for any practitioner or student of medicine.

¹ La sélection psychophysologique des travailleurs conducteurs de tramways et d'autobus. I Vol. pp. 210. Fr. 18. Dunod, Rouen-Paris, Paris, 1927.

² Le *Siccle Médical*, 10, Boulevard Poissonnière, Paris, Hémis-sel.

JEAN FRANCOIS COSTE.

Dr. Jean François Coste, chief physician to the French Army under Rochambeau which came to the assistance of the United States against England in the War of the Revolution, is recalled by Dr. J. E. Lane, of New Haven, Connecticut, in the *Military Surgeon for August*. Born in France in 1741, near the Lake of Geneva, he was the son of a physician, and was educated at Lyons and Paris. He met Voltaire at Ferney where he did such good work in an epidemic that Voltaire introduced him to the Prime Minister, Choiseul, who sent him to Nancy, and later to Calais. Thence he was appointed, in 1780, to Rochambeau's army, and leaving Brest on April 12th he arrived at Newport on July 11th—three months later. In America he published a pharmacopœia for the use of the hospitals; "the simpler the art of medicine," he said, "the more it is truly rich." Patients in the French hospitals were reported very neat and clean, though they did not recover better than the Americans. The French troops had good health, and Coste was thanked by Washington for what he did for the American hospitals. Returning to France he was moved from Calais to Versailles, becoming chief physician of camps and armies at the War Office. In 1790 he was appointed the first mayor of Versailles; "active, kind, and fatherly," he sought work for the people and kept the town quiet through the troubles of the time: no small success. His portrait hangs in the Hôtel-de-Ville, and shows a round face, high forehead, firm mouth, and deep-set eyes, with a kind and shrewd expression. He kept his head through the Terror, served on the health committee of the National Assembly, and went to the wars again with Napoleon till relieved of field duty in 1809, at the age of 68. He died in Paris ten years later, as chief physician of the Invalides. He had always stood up for the soldiers, and would not have economies made to their disadvantage. He was a physician, says Dr. Lane, "of ability and high character, whose long life was devoted to faithful and courageous service."

THE "A. & H." KNIFE.

THE new form of surgical knife with interchangeable blades here illustrated, is made by Messrs. Allen and Hanburys, Ltd., of 48, Wigmore-street, London, W.1, who state that the instrument is entirely of British manufacture, and that the handle is made of stainless steel. The scalpel blades, which are obtainable in three sizes, are easily and quickly inserted into or removed from

the handle, a slot and a pin being the means of attachment. The advantage of always having a sharp blade ready is, of course, obvious.

RADIOLOGY IN DENTISTRY.

THE Dental Board of the United Kingdom has published a series of four lectures delivered under their auspices last year. These lectures were: (1) The Physics of Radiology, given by Mr. G. W. C. Kaye, D.Sc.; (2) Instruments, Apparatus, and Radiographic Technique, by the late Dr. Robert Knox; (3) The Interpretation of Dental Skiagrams, by Dr. H. M. Worth; and (4) Ultra-violet Ray Treatment, by Dr. Leonard Hill. The object of the Dental Board in arranging these lectures has been to further post-graduate study. The lectures are not elementary; indeed, those who approach the subjects without some preliminary knowledge will find them rather advanced. On the purely radiographic side, highly instructive material is collected and nice judgment has been used in the choice of radiograms. Whether a collection of lectures of this sort will serve the radiographic needs of dentists quite as well as a systematic course, including practical instruction, is doubtful. Such a course would be an impossibility for many dentists, and the lectures here presented in one volume form a good substitute.

CENTENARY OF BIRKENHEAD GENERAL HOSPITAL.

THIS hospital began in 1828 as a dispensary in a small house provided by Mr. John Laird, the founder of the firm of Cammell, Laird and Co. In 1845 a new building was erected on a site given by Mr. Laird, and renamed the Birkenhead Hospital and Dispensary, and contained eight beds and two cots. The increase of popula-

tion soon made it inadequate, and in 1862 Mr. Laird built a new hospital of 50 beds at his own cost upon a site given by Mr. Thomas Brassey, the contractor. The building, then called the Birkenhead Borough Hospital, was enlarged in 1882; in 1901 another ward was added; there were further extensions in consequence of the War, and in 1926 the title was changed to the Birkenhead General Hospital. There are now 156 beds, and it is hoped to raise a centenary fund of £20,000 to open free from debt the new out-patients' department now being built. The *Birkenhead Advertiser* has issued an illustrated supplement detailing the history of the institution.

A NEW VENTILATING SYSTEM.

A DEMONSTRATION was recently given in London of a new ventilating system known as Anemostat, the essential feature of which is a spreader, enabling the air passing along a duct at high velocity to be introduced into a room at a uniform low velocity. By means of this device the air in a room may be changed as often as 10 to 15 times an hour without any sensation of draught, and with high efficiency, the loss of power at the spreader being negligible. Other devices of the ventilating system are dust separators of a simple but efficient type, washing apparatus for removing gases, vapours, and organisms from the air and permitting recovery of valuable or dangerous by-products. It is claimed that 90 to 99 per cent. of the organisms present in the incoming air can be removed. Arrangements are also provided for heating, cooling, humidifying, or drying the air so that it may be delivered at any desired temperature or humidity, as well as practically free from organisms and even the finest dust. The spray diffuser for humidifying can also be used for introducing disinfectants or therapeutic agents. It is stated that the sprayer breaks one gallon of water into over eleven million parts, the resulting mist being so fine and light that it penetrates to the smallest alveoli. The apparatus is handled in this country by Anemostat, Ltd., London.

ST. THOMAS'S HOSPITAL DINNER.

IN an account of this dinner on p. 952 of our last issue one of the speeches was attributed to Mr. G. Q. Roberts, late secretary of the hospital, who is at present in East Africa. The name of the speaker should have been given as Mr. George Roberts, and he is one of the senior almoners.

AN IMPROVED ATTACHMENT FOR ARTIFICIAL LIMBS.

OUR attention has been called to a new form of body-belt for the attachment of artificial legs. The advantages claimed for it are that the use of shoulder-straps is obviated, and in many cases the provision of a hip-joint and pelvic band for short stumps is rendered unnecessary. The belt is attached to the artificial limb by straps which hold it firmly in place on the stump, while freedom of movement is obtained whether sitting (there is no inconvenient strap directly at the back of the belt), standing, or walking. The wearer can extend the leg backward or forward, or move it from right to left without fear of displacement, while the two knees can be brought together or kept apart with ease. The makers are Messrs. W. R. Grossmith, Ltd., 12, Bury-street, Strand, London, W.C. 2, who will supply further particulars and demonstrate the appliance to any member of the medical profession.

"Overcrowding at Sheffield Infirmary."—In regard to a note under this heading in our issue of Oct. 27th, we are asked to state that the institution referred to is not the Royal Infirmary, Sheffield. "Through the long history of the institution it can truthfully be said," writes the general superintendent and secretary, "that two patients have never been placed in one bed."

THE LANCET: SUBSCRIPTION RATES.

INLAND	One Year	..	..	£2 2 0
	Six Months	..	..	1 1 0
	Three Months	..	..	0 10 6
ABROAD	One Year	..	..	2 10 0

	Three Months	..	..	0 12 6

Subscriptions not paid in advance are charged out at the published price of 1s. per copy, plus postage. Cheques and P.O.'s (crossed "Westminster Bank, Ltd., Covent Garden Branch") should be made payable to THE MANAGER, THE LANCET Offices, 423, Strand, London, W.C. 2.

A CLINICAL AND BIOCHEMICAL

Study

OF

ALLERGY.

By H. W. BARBER, M.B. CAMB., F.R.C.P. LOND.,

PHYSICIAN IN CHARGE OF THE SKIN DEPARTMENT,
GUY'S HOSPITAL;

AND

G. H. ORIEL, M.D. CAMB.,

ANDERSON DEMONSTRATOR OF CLINICAL CHEMISTRY AND
PARSON'S RESEARCH SCHOLAR, GUY'S HOSPITAL.

I.

THE word "allergy," as originally employed by Pirquet,¹ has really a narrower application than others have given to it, for, as Darier² points out, although it includes all forms of acquired hypersensitiveness, it excludes inborn hypersensitiveness or idiosyncrasy. This distinction, however, is hardly of practical importance or, indeed, valid, and with Doerr, Zinsser, Wells, Duke,³ and others we use the term in its wider sense to indicate almost all forms of hypersensitiveness. Moreover, we regard as profitless the discussions that have arisen as to whether or not the so-called allergic conditions, such as hay-fever, asthma, and urticaria, should be regarded as anaphylactic reactions or whether they differ essentially from true anaphylaxis, as produced experimentally in animals or as it may occur accidentally in man. Lewis⁴ says:—

"It is not universally accepted that this phenomenon (protein sensitivity) is identical with the anaphylactic reactions that have become models in animal experiment, though it is certainly not to be doubted that it holds much in common with the latter."

The important fact is that many of the clinical symptoms to which sensitised persons are liable are identical with those seen in animals with anaphylactic shock—for example, contraction of the pilo-motor muscles with erection of the hair follicles, paroxysms of sneezing and coughing, pruritus, urticaria, respiratory distress consequent upon the contraction of the smooth muscle of the bronchioles and œdema of the bronchial mucous membrane, vomiting, diarrhoea, diuresis, and epileptiform convulsions. The following list includes the majority of symptoms which are certainly or probably of allergic origin:—

Cutaneous.—Urticaria; true infantile eczema; certain forms of eczema occurring after infancy; certain forms of pruritus; prurigo of the Besnier type; prurigo of the Hebra type; prurigo of the simple type; prurigo nodularis; urticaria papulosa (lichen urticatus, strophulus); light-sensitisation of the adult type; dermatitis herpetiformis (probably).

Subcutaneous.—Angeioneurotic œdema.

Respiratory.—Paroxysmal rhinitis, of which hay fever is one of the commonest examples; asthma.

Gastro-intestinal.—Certain forms of vomiting and diarrhoea; cyclical vomiting.

Nervous.—Migraine; epilepsy (probably).

Articular.—Paroxysmal hydrarthrosis.

This list, although it may appear formidable, is doubtless incomplete. Freeman⁵ includes functional albuminuria and—tentatively—dermographia and paroxysmal colitis. Cases have been recorded in which functional albuminuria ceased when certain articles of food—e.g., milk—were excluded from the dietary. We are tempted also, with Freeman, to include ichthyosis, since, as has been pointed out by one of us,⁶ it is so commonly seen in those patients who from earliest childhood manifest concurrently or in succession multiple symptoms of the allergic state. Many of them have such characteristic physical and psychical attributes, and exhibit a syndrome of symptoms so constantly, that one is justified in classing them as a type apart. Indeed the practical eye will recognise a person belonging

to this type at a glance; he represents the allergic subject par excellence. The cardinal symptoms comprising the syndrome are: Besnier's prurigo, asthma, and eczema; a considerable proportion of the patients are ichthyotics, and other allergic symptoms, such as urticaria, angeioneurotic œdema (an unnecessary term, since it is merely a subcutaneous form of urticaria), and hay-fever may occur. The great majority have suffered from true infantile eczema, which may be preceded by ichthyotic dryness of the skin; at about the age of two years the infantile eczema merges into the prurigo of Besnier, though the latter may develop without a previous eczema and may even occur for the first time in adolescence; sooner or later asthmatic symptoms—usually diagnosed at first as "bronchitis" or "broncho-pneumonia"—appear, and paroxysmal rhinorrhœa and urticaria are not uncommon. It is in patients of this type that well-marked positive cutaneous reactions are obtained with various foreign proteins, and multiple positive tests are the rule. To cite but one example:—

CASE 1.—A man aged 42; family history of eczema; ichthyosis on the father's side. Had infantile eczema. Asthma began at the age of 2 years. Asthma and irritation of the skin provoked by contact with horses and cows; also asthma with catarrhal infections. Severe urticaria and angeioneurotic œdema from brazil nut, which once nearly caused death from œdema of the glottis, when taken accidentally. Has ichthyosis and prurigo of the Besnier type in antecubital fossæ, popliteal spaces, wrists, and face. Cutaneous tests: horse + + +; cattle +; dog +; sheep +; brazil-nut + + +.

Definition of Prurigo.

Although many dermatologists will doubtless disagree with us, we employ, with Darier,⁷ the term *pruritus* as a synonym of itching, and *prurigo* to indicate certain definite changes that take place in the skin as a result of a long-continued pruritus and consequent rubbing and scratching. Not every person, however, with pruritus, even of long-standing, necessarily develops prurigo. The changes that actually occur in the skin differ somewhat in the various forms of prurigo; they comprise (1) the prurigo papule or nodule, (2) the characteristic modification of the appearances and structure of the skin termed by Besnier *lichenisation*, and described in minute detail by Brocq⁸ as *lichenification*. In some clinical varieties of prurigo the papules predominate, in others lichenification, but both types of lesion are often present in the same case. The chief varieties of prurigo may be classified as follows:—

1. *Prurigo simplex acutus*: Urticarial wheals with central papules.—Syn: Urticaria papulosa (Kaposi, Dubring, Crocker); lichen urticatus (Bateman); lichen simplex acutus (Vidal); strophulus pruriginosus (Hardy); prurigo infantilis (Hutchinson, Pye-Smith).

2. *Prurigo simplex*: Lichenification.—Syn: Névrodermite (Brocq), (a) circumscribed form (syn. lichen simplex chronicus (Vidal), and (b) diffuse form.

3. *Prurigo of Besnier (Rasch)*: Lichenification.—Syn: Prurigo-asthme (Sabouraud).

4. *Prurigo of Hebra*: Papules with some lichenification.

5. *Prurigo nodularis*: Nodules.

The prurigo of Besnier is a definite entity. Besnier,⁹ in his original description, termed it "prurigo diasthésique." He emphasised the following features: (1) the violence and paroxysmal nature of the itching, the paroxysm being usually nocturnal and the intensity often subject to seasonal variations; (2) the localisation to the joint flexures, the skin in these situations becoming lichenified, with moisture and fissuring during the more intense paroxysms of itching; (3) the coexistence of asthma, hay-fever, and gastro-intestinal disturbances; (1) the chronicity of the condition and its resistance to treatment.

Hodara¹⁰ in 1902 described a number of cases, with a detailed analysis of the various elementary lesions and the clinical forms of eruption that may be met, but it is doubtful whether all his cases were genuine Besnier's prurigo. Rasch¹¹ has given one of the best descriptions of the condition. He had previously referred to it in his book on diseases of the skin (1903), and he was the first to suggest the term

"prurigo of Besnier." He emphasises the following points:—

1. The familial incidence. (Although we have met with it in more than one member of a family it is far commoner to find other allergic manifestations—e.g., infantile eczema, asthma, hay-fever, urticaria, lichen urticatus, migraine, &c.—in the parents and their near relatives, or in other members of the same generation.)
2. The onset in early childhood (it frequently, of course, follows infantile eczema) much more rarely at or after puberty.
3. The intensity of the itching and its nightly exacerbation (nocturnal paroxysms are the rule in allergic conditions).
4. The extreme chronicity and resistance to treatment.
5. The coincidence of asthma, which usually accompanies the paroxysms of itching, rarely alternates with them.
6. Its occurrence in nervous, pale, restless children.
7. In adults its occasional coexistence with light sensitisation.
8. Its clinical distinction from the true prurigo of Hebra, which spares exactly those situations most affected in Besnier's prurigo—viz., the flexures of the joints, the neck, and the face. Rasch points out that the latter was really first described in 1884, eight years before Besnier published his original observations, by Hans Hebra as "dermatomycosis diffusa flexurarum," although he wrongly ascribed to it a mycotic origin. Strictly speaking, therefore, it should be known as the "prurigo of Hans Hebra," but, since his father's name has been given to another form of prurigo, confusion might arise.
9. The therapeutic effect of a strict lacto-vegetarian diet. (This point will be referred to later; it is one of very great importance in relation to our researches into the aetiology of the condition.)

Sabouraud¹² gives a clinical description of Besnier's prurigo in its association with asthma, labelling it "le prurigo-asthme."

Recently Haxthausen¹³ has contributed an important article in which he briefly surveys the literature and records some observations of his own in a series of 38 cases, 24 of which were males.

He remarks that the influence of heredity was not very apparent in his patients, but this was doubtless because he did not realise that Besnier's prurigo is merely one of numerous manifestations of the allergic state. Seven of his cases were asthmatics and seven ichthyotics, but it did not appear that ichthyosis was more frequent in the asthmatics than in the others. One patient also had hay-fever, and during the hay-fever period the cutaneous lesions disappeared. Haxthausen observed that practically all his patients recovered in hospital on a lacto-vegetarian diet combined with suitable local treatment, and there were never any sudden exacerbations or remissions so long as the patient remained in hospital; they usually occurred, however, as soon as he returned to his normal life. This, as every clinician is aware, is characteristic of allergic conditions. Haxthausen, however, quotes one case—a young man with asthma and Besnier's prurigo—who was admitted to a dermatological clinic and placed on a strict lacto-vegetarian diet; in a few weeks both the asthma and prurigo disappeared. But on removal to an ordinary medical ward for treatment of his asthma he was given the usual full diet, with the result that his symptoms returned, only to disappear again when the lacto-vegetarian régime was renewed. With this in mind Haxthausen proceeded to perform cutaneous tests with various proteins—food substances, animal pellicles, bird feathers, plant seeds, and pollen, &c.—in a series of 15 of his cases; 12, or 80 per cent., gave positive reactions. In ten cases multiple reactions were obtained. All the asthmatic cases (3) and one hay-fever patient gave strongly positive tests. Patients with other dermatoses were also tested similarly; apart from slightly positive reactions in a few cases of chronic urticaria and lichen urticatus, the only other condition which gave well-marked positive tests was infantile eczema (4 cases out of 11). An attempt was made to determine a relationship between the prurigo and the substances to which the patients reacted, with some apparent success.

Baagøe¹⁴ has also published an article on Besnier's Prurigo in Asthma, in which he records 15 cases of Besnier's prurigo, 13 of which were also themselves asthmatic, one was the brother of an asthmatic subject, and one the child of an asthmatic parent. Six of these cases were also ichthyotic, and 11 had previously had infantile eczema. In a few cases there was also lichen urticatus, or ordinary urticaria due to food sensitiveness. Cutaneous tests were performed in 14 of these cases, and some positive reactions were obtained in all. He concludes that

Besnier's prurigo, like asthma and urticaria, is an anaphylactic phenomenon.

All these observers recognise Besnier's prurigo as a definite clinical entity, distinct from Hebra's prurigo which has a different distribution, involving the extensor surfaces and sparing the joint flexures and face, the parts most commonly affected in Besnier's prurigo. Brocq unfortunately confuses matters by referring to the latter as "prurigo dit de Hebra, variété française," and in his *Cliniques Dermatologiques* he there describes and illustrates a typical example of Besnier's prurigo in a child, affected also with asthma and bronchitis. Veryrières et Jumeon¹⁵ in an article entitled "L'asthme infantile intrigué de dermatoses prurigineuses," divide the cutaneous manifestations that accompany the asthma into "prurigo diathésique type Besnier" and "prurigo chronique vrai, forme atténuée de prurigo de Hebra"; they also remark that attacks of papular urticaria (strophulus) may precede the onset of the asthma. While recognising that in the prurigo of Besnier lichenification in the antecubital fossæ and popliteal spaces is characteristic, whereas in Hebra's prurigo it is the extensor surfaces of the limbs that are most affected, they nevertheless state that Brocq refers to the latter as "prurigo de Hebra à type français," but, as stated above, the case described by him under this title was unquestionably one of Besnier's prurigo.

We do not wish to labour the point unnecessarily, but we would insist that *clinically* the prurigo of Besnier and the prurigo of Hebra are entirely different, both as regards their localisation, the type of elementary lesion, and the *tout ensemble* of the fully developed eruption. The latter condition is much the rarer of the two. Both are unquestionably allergic in origin, and there are many points of resemblance between them, but they are nevertheless distinct morphologically and clinically, and should not be confused with each other. We would here emphasise two features which have not, perhaps, received the attention they deserve: pigmentation, and the erection of the pilo-sebaceous follicles on certain parts of the skin. They are not, of course, especially characteristic of Besnier's prurigo, but, on the contrary, are commonly seen in what may be called the prurigo group of eruptions; the simple papular prurigo, so frequently met with in adults, which involves particularly the neck and the extensor surfaces of the limbs; the prurigos of Besnier and Hebra; prurigo nodularis; dermatitis herpetiformis; light sensitisation of the adult type; and even urticaria papulosa, particularly when of the bullous type. In Besnier's prurigo the areas of lichenification are bordered by a zone of pigmentation, the hue and intensity of which vary according to the individual. In severe cases it is fawn-coloured and hardly distinct from the general sallow tint of the skin as a whole; in others, it is so deep a brown, particularly on the neck, as to recall that of Addison's disease. Apart, however, from the lichenified areas there may be increased pigmentation of practically the entire skin. There can be no question but that this pigmentation is due, like the erection of the pilo-sebaceous follicles and the prurigo itself, to involvement of the sympathetic or endocrine-sympathetic system. The erection of the pilo-sebaceous follicles ("goose-skin"), due to stimulation of the sympathetic fibres supplying the pilo-motor muscles, is one of the earliest cutaneous symptoms of the sensitised state, whether it be the skin itself that is sensitised (for example, to external irritants such as paraphenylenediamine or other chemicals) or whether the cutaneous response be part of a general systemic sensitisation—e.g., food poisoning, and drug intoxications, as from salvarsan or one of the gold-compounds. It is, perhaps, in cases of prurigo that the erection is most apparent. Jacquet¹⁶ has insisted on the exaggerated contractility of the arrectores pilorum in prurigo, urticaria and some cases of eczema, and their actual hypertrophy in prurigo; this hypertrophy has also been described by Unna¹⁷ in Hebra's prurigo.

We would also remark upon one very characteristic feature of the majority of allergic symptoms, namely, the influence upon them of psychical factors—e.g., annoyance, worry, emotion and nerve-exhaustion, and of the patient's surroundings. The susceptibility of an asthmatic to climatic and domiciliary changes is common knowledge, but the same holds good for other manifestations of the syndrome. Hallam¹³ has rightly emphasised the fact that children with urticaria papulosa invariably lose the eruption in hospital, and that recurrence does not take place so long as they remain there. One of us (H. W. B.) recently admitted a boy to his ward with severe and typical prurigo of the Hebra type; the child entirely lost his itching, and the eruption cleared up after a week's sojourn in hospital, although no treatment of any kind was given. Within 12 hours of his return home the itching returned, and a week later the prurigo had become re-established. Under hospital conditions, too, an asthmatic often ceases to have attacks, but this is not constant. Children with infantile eczema or Besnier's prurigo also usually improve considerably, even without treatment, either dietetic, local or internal, only to relapse on their return home, but in them the effect of hospitalisation is not nearly so striking as in urticaria papulosa, Hebra's prurigo, or asthma. In adult patients with prurigo of the simple type we have often observed that a few days away from the worry of professional or domestic life, even though they eat and drink less carefully than at home, may lead to an entire cessation of itching. We will not discuss the explanation of this remarkable effect of hospitalisation or a change of surroundings, but, in view of what is to follow, we will merely point out that the improvement in the clinical condition is accompanied by a corresponding change towards the normal in the metabolism of the patient.

In the same way the influence of worry, domestic unhappiness and other psychical disturbances in precipitating the paroxysms of allergic symptoms is very striking; it reminds us that the part played by the vegetative nervous system, which is so susceptible not only to toxic substances of various kinds but also to psychical trauma, plays an essential rôle in the genesis of that highly complex phenomenon the allergic reaction. We must never lose sight of the fact that patients with a marked tendency to the development of allergic reactions have a psychical complex that is quite distinctive and that their vegetative nervous system, which controls their digestive and metabolic functions, is very easily disturbed, not only by bacterial infection, foreign proteins or protein derivatives and chemical poisons, but by fatigue or emotion as well.

BIOCHEMICAL INVESTIGATIONS.

One very significant fact may be emphasised at the outset, namely, that from the biochemical point of view the same essential cycle of events has been found to occur in all the allergic conditions so far investigated. There would seem, in fact, to be a "biochemical formula" common to all of them and, in spite of the differences in the actual clinical symptoms, the underlying metabolic changes are essentially the same.

Our studies are based on repeated examinations of the blood and of the urine, both during the phase of active symptoms and in periods of quiescence. We recognise a pre-paroxysmal, a paroxysmal, and a post-paroxysmal stage, and we are now able, merely from examination of the blood and urine, to state with considerable confidence in which stage the patient was when the given specimens were taken. The investigations were begun in order, if possible, to determine the part played by the liver in allergic conditions. The writings of Widal and his co-workers,¹⁴ the researches of Manwaring¹⁵ on experimental anaphylaxis, and, from the clinical standpoint, the views of Monod¹⁶ and others on the pathogenesis of asthma are well known. Since, however, in allergy one is dealing with protein sensitisation, one naturally looks for disturbances of the hepatic function in

protein metabolism. We shall not discuss the value or otherwise of the hæmoclastic-crisis test of Widal, Abrami, and Ivanesco. It has been studied, particularly by Brack,¹⁷ in cases of prurigo and related conditions, and Wilson¹⁸ states that it is positive in asthma, epilepsy, and certain infections. Shaw,¹⁹ however, concludes that, so far as the leucocyte count is concerned, "the hæmoclastic test lacks a theoretical basis, and in practice is of no value in the diagnosis of hepatic insufficiency." Marcel Labbé²⁰ considers that the study of the amino-acid excretion in the urine is one of the most reliable tests of hepatic function. Under normal conditions it is small and varies according to the dietary, being practically nil on a strict vegetarian régime. Hyperaminoaciduria is met with particularly in hepatic disease—e.g., in alcoholic cirrhosis. Labbé and Bith²¹ have also shown that it occurs in diabetes with acidosis, but it is only indirectly an indication of acidosis. It is merely a sign of the diabetic disturbance of nitrogenous metabolism.

Numerous tests have been devised for investigating the various and important functions of the liver, and for a detailed and comprehensive analysis of the methods employed we would refer to the classical monograph of Noël Fiessenger and Walter.²² For our purpose it seemed reasonable to suppose that the estimation of the amino-acid content of the blood might afford a reliable index to the efficiency or otherwise of the liver in protein metabolism. For this Folin's²³ colorimetric method was employed, using sodium β -naphthoquinone-sulphonic acid as reagent.

It appears, from our investigations and from those of others, that the average normal figure for the amino-acid content of the blood is from 4.0 to 6.5 mg. per 100 c.cm., the latter figure being distinctly a "high-normal." In order to determine the effect of a meal containing plenty of protein, "protein-tolerance tests" were performed in normal subjects and in those with allergic symptoms. A determination of the amino-acid content of the blood was made before breakfast or several hours after a meal, and a mixed meal containing various proteins was then given and estimations made one, two, and three hours afterwards, e.g.:—

CASE 2.—Normal subject. Before breakfast 3.7 mg. per 100 c.cm.; one hour after breakfast 4.7 mg., which figure remained constant two and three hours afterwards.

CASE 3.—Normal subject. 5.0 mg. before a meal; 5.8 mg. afterwards.

CASE 4.—Normal. 4.0 mg. before; 5.6 mg. afterwards.

CASE 5.—Case of dermatographism and urticaria. 5.0 mg. before a meal; one hour afterwards 5.5 mg.; two hours afterwards 6.2 mg., when there was slight urticaria; three hours afterwards 5.8 mg., when the urticaria had disappeared.

CASE 6.—Case of asthma and prurigo. Fasting 7.0 mg.; one hour after meal 7.2 mg.; two hours after 7.4 mg.; three hours after 7.2 mg.

There is, therefore, a slight temporary rise in the amino-acid content of the blood after a protein meal, both in normal subjects and in others. A large number of estimations have been carried out in patients with allergic manifestations, the majority of cases investigated being classical examples of the asthma-hay-fever, eczema, prurigo syndrome; in a considerable proportion more than one of these various symptoms were present. In this group, which for brevity's sake we will term the asthma-prurigo group, a high amino-acid content of the blood was found to be constant in untreated cases, with this reservation: the patients were seen as a rule when one or other of their symptoms, usually prurigo, were active. Normal figures may be obtained after dietetic and other treatment, and probably also during the remissions that occur so often and so inexplicably in these patients.

CASE 7.—A man of 35, an ichthyotic, with a family history of asthma and migraine, suffered from infantile eczema and later asthma and prurigo of the Besnier type. In December, 1927, he was having moderately severe

asthmatic attacks, with nocturnal exacerbations of itching. The amino-acid content of the blood drawn in the afternoon—a period of quiescence—was 7.0 mg. per 100 c.cm. After a fortnight's dietetic and other treatment he was free from asthma and itching. The amino-acid figure was 5.8—i.e., normal. Treatment was suspended, and he returned in January, 1928, having had slight asthma and itching; amino-acid figure 7.0. Early in March he had a severe relapse after a gastro-intestinal upset; amino-acid figure 9.3. Treatment again instituted; at the end of a fortnight marked improvement; amino-acid figure 7.0.

It is our impression that in cases of Besnier's prurigo, with or without asthma, the amino-acid content of the blood tends to be high, even during periods of comparative freedom from itching. Thus Case 1, with ichthyosis, asthma, Besnier's prurigo and urticaria, and multiple sensitisation to horse and other animals and to brazil-nut, nevertheless had an amino-acid figure of 9.8 during a period of almost complete absence of symptoms.

CASE 8.—A little boy with Besnier's prurigo and formerly infantile eczema and asthma had an amino-acid figure of 8.2 at a time when the prurigo was slight.

CASE 9.—A little girl with asthma, hay-fever, horse sensitiveness, eczema, prurigo, and urticaria was seen during one of her best periods, when she was having no asthma and only slight itching; the amino-acid figure was 9.3.

Of 41 patients belonging to this group, in nearly all of whom there was a combination of asthma or hay-fever with prurigo of the Besnier type and several of whom were ichthyotics, the average figure for the amino-acid content of the blood was 8.8. The highest figure in this series was 11.0, the lowest 7.0. In 13 cases of urticaria the average amino-acid figure was 7.8. In some of these the examination was made during the active, in others during a quiescent stage. In some cases of urticaria and of asthma without prurigo the amino-acid figure may be normal, or nearly so, in the intervals between the attacks, but it rises rapidly during the paroxysms. One case of urticaria gave 6.4, rising during an attack to 11.8, another 5.0 rising to 7.4 and 9.3. Some of our urticarial patients with nocturnal attacks have given figures well within normal limits during the daytime; others, however, have given raised figures even when no eruption was present. A patient with angioneurotic oedema gave 6.0 in an interval between attacks, rising to 8.2 during one.

The conclusions at which we have arrived from investigations made in a large number of patients are as follows: (1) During the acute paroxysms of allergic manifestations the amino-acid content of the blood is raised. (2) In cases of prurigo of the Besnier type, in which asthma, hay-fever, and ichthyosis were often also present, high figures were usually obtained even during periods of comparative freedom from symptoms. The figure rose still higher during the paroxysms of itching. (3) In cases of simple urticaria or of angioneurotic oedema, and of asthma without prurigo, the figure may be normal or nearly so in the quiescent stage, but is constantly raised during the attacks.

A raised amino-acid content of the blood has also been found in cases of light sensitisation of the adult type (average figure in 16 cases 7.9), in four cases of dermatitis herpetiformis, in some cases of simple prurigo occurring for the first time in adult life, in prurigo nodularis (three cases), in certain cases of eczema of the "gouty" type associated with a high blood pressure, in a case of dermatitis exfoliativa of unknown cause, in cases of salvarsan poisoning with jaundice, in one patient with cirrhosis of the liver, and in a case of intermittent hydrarthrosis associated with psoriasis. On the other hand, normal figures have been obtained in uncomplicated psoriasis, in two cases of cirrhosis of the liver, in one case of toxic jaundice following tonsillectomy, in a case of sarcoid, and in two of alopecia areata. In healthy, normal subjects the figures are remarkably constant. In experimental anaphylactic shock Hisanobu²⁹ found a rise in the blood of total non-protein nitrogen and amino-nitrogen.

We have not as yet estimated uric acid and creatinine in the blood in a sufficient number of cases to enable us to draw any definite conclusions, but it appears that during the acute paroxysms their quantity is raised. At all events they are excreted in increased amounts in the urine at and during the period immediately following the paroxysms. Such an increase of non-protein nitrogen excretion has also been observed after attacks of acute urticaria by Longcope and Rackemann.³⁰

The significance of a raised amino-acid content of the blood will be discussed later. We know that it occurs in anaphylactic shock, and in the proteose intoxication which Whipple and Van Slyke³¹ have shown to take place in experimental intestinal obstruction and in which the non-protein nitrogen in the blood is greatly raised.

Chlorides.

In serum disease, Pirquet and Schick³² showed that there was a relative increase in weight, which they considered to be due to retention of fluid. Rackemann, Longcope, and Peters³³ demonstrated that there is, during the active stage of serum disease, a marked but transient retention of chlorides and water, associated sometimes with a slight albuminuria and cylindruria, and occasionally with an impairment of the excretion of phenolsulphonaphthalein by the kidneys. They stated that in patients with oedema and a gain in weight during serum sickness the plasma chlorides were below normal. Longcope and Rackemann³⁴ also investigated six cases of urticaria, both during and after attacks. In one patient sensitive to beef and sheep protein the attack of urticaria was associated with a rise in blood-urea, a decrease in the phthalein output, suppression of urine, and almost complete suppression of chloride and nitrogen excretion. Immediately after recovery the nitrogen and chloride excretions were excessive, and the blood-urea, the phthalein output, and the water exchange returned to normal. During this period there was a loss of almost 8 lb. in weight. These results correspond with our own findings in allergic diseases. In infantile eczema, Lust³⁵ and Lederer³⁶ found at times a considerable increase in the water content of the blood as compared with that of normal infants, and wide and rapidly occurring fluctuations of the water-content were characteristic. These fluctuations appeared to depend on alterations in the metabolism of mineral salts. Freund³⁷ found that eczematous infants showed a much greater retention of chloride than non-eczematous infants on the same diet. This retention of chloride was coincident with a rapid gain in weight due to a simultaneous water retention. Meyer³⁸ found that if eczematous infants were underfed there was a much greater excretion of mineral salts than in normal infants on the same diet.

In considering the chloride content of the blood a distinction must be drawn between the serum content and the whole blood content. The chloride content of a given volume of serum is greater than that of the same volume of whole blood, showing that normally the serum chloride exceeds that in the corpuscles. The normal readings are fairly constant; a series of estimations in normal controls gave figures varying from 570 to 585 mg. per 100 c.cm. of serum, and 451 to 495 mg. per 100 c.cm. of whole blood. These may probably be taken to represent the normal limits. The chloride content is estimated as the chlorine-ion and the result expressed in terms of NaCl, although the actual combination of the chlorine-ion varies in the serum and the red cell; it is probably present as NaCl in the serum, and KCl in the red cell.

In acute and chronic allergic manifestations the whole blood chlorides seem to be markedly diminished during the paroxysms, and the reduction of the corpuscle content is greater than that of the serum content. This reduction was most constantly found in the asthma-prurigo group, and varies with the exacerbation or remission of the symptoms. In simple urticaria the chloride reduction takes place,

like the increase in blood amino-acid, during the attacks and usually returns to normal or may be higher than normal in the intervals. (Table I.)

TABLE I.—Showing Reduction of Whole Blood Chloride.

Disease.	Estimated as NaCl.		
	Amino-acid content of the blood.	Serum chloride†	Whole blood chloride†

* Quiescent stage. † as NaCl.

One case of severe prurigo of the Besnier type, associated with occasional attacks of asthma, was investigated at various times. (Table II.)

TABLE II.

Date in 1928.	Condition.	Amino-acid.	Serum NaCl.	Whole blood NaCl.
Mg. per 100 c.cm.				
April 24th	After being for some time on a vegetarian diet, fairly free from itching.	5.1	577	396
May 1st	After sal volatile, pot., bicarb. and urea. Much better.	—	610	430
May 5th	Relapse with severe itching and asthma following a catarrhal infection with some pyrexia.	7.0	516	363
May 13th	Asthma gone, still itching.	7.7	—	396
June 8th	Worse (menstruating).	9.3	561	428

A case of angioneurotic oedema gave the figures shown in Table III.

TABLE III.

		Before attack.	During attack.
Mg. per 100 c.cm.			
Amino-acid	5.8	—	8.2
NaCl (whole blood)	480	—	396
NaCl (serum)	580	—	577

These blood findings correspond to those of Haden and Orr¹² in experimental high intestinal obstruction. They found an increase in the non-protein nitrogen and a diminution of blood chloride. They concluded

that the symptoms of toxæmia were due to proteoses, absorbed through the damaged intestinal mucosa, and that chloride was utilised to neutralise these toxic substances. This view is similar to that held by Richet,⁴⁰ who showed that experimental anaphylactic shock could be prevented by the previous injection of sodium chloride.

[In a second article the authors deal with the study of the urine in allergic states and with the principles of treatment, with a summary of their conclusions.]

MEDWAY INFIRMARY.—A new wing of the Medway Workhouse Infirmary at Chatham, entirely for women patients, has been opened by Mr. F. A. Chappell, the chairman of the board of guardians. It will be known as the Medway Hospital, and will not be deemed to be a poor-law institution. The cost has been £37,000, and there is accommodation for 98 patients, of whom the phthisis pavilion will take 12, and the isolation pavilion eight.

KENSINGTON GENERAL HOSPITAL.—The new buildings of the Kensington, Fulham, and Chelsea Hospital are to be begun forthwith. The plans, prepared by Sir Aston Webb and Son, provide for the work to be done in three sections, and the first two are now to be taken in hand. They will provide 65 beds, two operating theatres, and the greater part of the new out-patient department. The old hospital, which was opened in 1857, and has since been twice enlarged, has only 19 beds; the new building, when completed, will contain 107 beds. This is the only hospital in the three boroughs of Kensington, Fulham, and Chelsea, with a population of half a million, for general medical and surgical cases.

THE PHENOMENON OF RETICULATION AND THE ALTERATION IN SIZE OF THE RED BLOOD CORPUSCLES AFTER LIVER THERAPY.*

By L. S. P. DAVIDSON, B.A. CAMB., M.D.,
F.R.C.P. EDIN.,

ASSISTANT PHYSICIAN, ROYAL INFIRMARY, EDINBURGH,
AND LEITH HOSPITAL;

AND

J. G. MCCRIE, M.B., CH.B. EDIN.

(From the Bacteriology Department, University of Edinburgh.)

ALTHOUGH the staining of red blood corpuscles by vital methods was described by Ehrlich in 1880¹ and was subsequently investigated by various workers, it is only recently that the technique has been widely adopted as a clinical procedure. The remarkable therapeutic advance in the treatment of pernicious

layer of dried cresyl blue, and a second cover-slip is superimposed. After 30 to 60 seconds the cover-slips are drawn apart and allowed to dry. The films are then counterstained with Leishman or Jenner (or other suitable fixative and stain), dried, and mounted in balsam.

When a film treated by either of the above methods is examined certain of the red cells are observed to contain within their cytoplasm blue-staining material in the form of granules, rods, filaments, or even definite networks. It is to these cells that the term "reticulated red cells" or "reticulocytes" is applied. A differential count of the red cells may be made and the number exhibiting reticulation expressed as a percentage of the total number of cells counted. The nature of the "reticular" material is still a matter of doubt. Some observers have regarded the phenomenon as being purely necrobiotic; others have held that the material demonstrated by vital staining exists *in vivo* as a definite constituent part of the cell. If the view is accepted that during the course of development the erythrocyte loses its nucleus by its extrusion entire and not by breaking up intracellularly, it would appear that the reticulum is a pre-existing cytoplasmic

* The index of anisocytosis is the ordinary coefficient of variation. In calculating the value Sheppard's adjustments have been used.

anæmia by means of liver and liver extracts has re-awakened interest in the phenomena revealed by vital staining. Since the response of a case of pernicious anæmia to treatment can be most accurately and rapidly estimated by the degree of reticulation appearing in the circulating blood, it is essential that methods of vital staining should become routine clinical procedures. Various methods have been described. Hawes² employed aqueous cresyl blue as the dye of choice, but included in his paper a description of various other staining methods, including those of Chauffard and Feissenger (Pappenheim's stain); Biffi (boracico-blue of Gosio); Vidal, Abrami, and Brulé (polychrome blue of Unna); and Biondi (alcoholic cresyl blue). The technique employed by the writers is a modification of that of Hawes² and Dameshek,³ the stain used being brilliant cresyl blue in 0.3 per cent. solution in absolute alcohol. Their procedures have been described in detail elsewhere⁴ and will here only be summarised as follows:—

(1) *Fresh Specimens.*—A drop of the dye in solution is spread on a slide and the alcohol allowed to evaporate. Over this a film of blood is drawn in the usual way, and a cover-slip is immediately placed upon it, slight pressure being employed if necessary. Such a preparation remains fluid for some hours.

(2) *Permanent Preparations.*—A small drop of blood is taken upon a cover-slip which has been charged with a thin

structure and not a product of nuclear degeneration. Strong support has been given to this hypothesis by the recently published work of Valentine.⁵ If, on the other hand, the reticulum is derived from nuclear material, it should have an affinity for dyes which stain chromatin—e.g., methyl green. The writers were unable to demonstrate this affinity. It is possible, of course, that in process of degeneration the nuclear chromatin has been altered into some new substance.

It is now agreed that the reticulated cells seen in vitally stained films are the same cells as those which show polychromasia in films fixed before staining. A direct numerical relationship between polychromatic and reticulated cells has been repeatedly demonstrated by the writers. It has been suggested that the appearance of reticulation may be an artefact due to coagulation or condensation of the diffuse basophil material in the cell by the action of a powerful basic stain, such as cresyl blue, acting on the cell previous to fixation. Even if this be the case, it in no way detracts from the value of vital staining, since the percentage reticulocyte count is the simplest and most accurate method of estimating the number of young cells entering the circulation. The writers have observed that the first reticulocytes to appear in the circulation have a well-marked reticulum, centrally situated and of so dense a structure that it may be difficult to distinguish the appearance from that of nuclear karyorrhexis. The microscopic evidence thus appears to be in favour of the theory that reticulation

* Part of this work has been carried out with the aid of a grant from the Medical Research Council.

is directly connected with nuclear degeneration. On the other hand, reticulation has occasionally been observed in nucleated cells. The whole subject must still be viewed with an open mind.

However doubtful may be the physical basis of "reticulation," there appears to be no doubt that the "reticulocytes" are the cells which have most recently entered the circulating blood from the bone-marrow. It is obvious, therefore, that their presence is in no way characteristic of any individual pathological condition, but is merely evidence of blood regeneration. Thus the writers find that in normal persons they are present to the extent of 0.5 per cent. of the total number of red blood corpuscles. In simple secondary anemias following hæmorrhage (e.g., menorrhagia, hæmatemesis), the percentage may rise as high as 35, depending on the amount of blood lost and on the functional efficiency of the bone-marrow. In acholuric jaundice, a disease associated with a large and continuous blood destruction, the response of the bone-marrow is evidenced by a percentage of reticulocytes of 15 to 40 over long periods. In all other conditions associated with anaemia—e.g., malaria, cancer, gastric ulcer, &c.—reticulation will be found in proportion to the degree of anaemia and the ability of the bone-marrow to respond.

In pernicious anaemia the subject is of especial practical importance in that a rapid increase in the numbers of reticulocytes in the circulating blood is direct evidence of the efficacy of the therapeutic agent used, and is a valuable guide to prognosis.

The Measurement of the Red Blood Corpuscles in Pernicious Anaemia and other Pathological Conditions.

The measurement of the diameters of red blood corpuscles is a matter of considerable difficulty. When the absolute size of the cells is to be considered stained films cannot be employed, since the process of drying produces changes of unknown extent in the diameters. For absolute measurement the cells should be suspended in plasma and a photographic method used, such as that recommended by Ponder and Millar.² Even with the greatest care these investigators admit that an error of 0.2μ occurs. In the measurement of dry films by the method of

fail to agree on what is the actual average diameter of a normal red blood corpuscles. The writers, however, were not concerned primarily with the study of the exact measurement of red blood corpuscles. The objects of the investigation were:—

(a) To test the accuracy of the impression that had been formed that the reticulocytes, as seen both in fresh specimens and permanent preparations, were larger than the average adult red cell.

(b) To demonstrate the alteration in the size of the red blood corpuscles in pernicious anaemia after treatment with liver or liver extract.

(c) To gain some definite idea of the size of the cells in various types of secondary anaemia.

A projection method was employed similar to that of Price-Jones. Permanent preparations were used of the type above described, the counter-stain being Jenner, followed by dilute Giemsa. Since the method of fixing and staining was in each case the same, the experimental error would appear to be a constant. Films prepared in this way were projected by means of a mirror on to a sheet of white glazed paper. All the cells from several fields were outlined in pencil and subsequently measured. The adjustment of the apparatus was such that the magnification was exactly 1000, millimetre measurements in the projection thus representing measurements of 1μ in the film. Measurements were carried out by means of geometrical dividers, between 200

FIG. 1.

Blood film (fresh specimen), vitally stained, from a case of gastric ulcer in which a severe hæmatemesis had occurred 36 hours previously. Note: (1) The small size of the mature red blood corpuscles, due to the previous secondary anaemia. (2) The large size of the reticulocytes, whose mean diameter is nearly 9μ . ($\times 1000$.)

FIG. 3.

FIG. 4.

Blood film (fresh specimen), vitally stained, from a rabbit from which 50 c.cm. of blood had been removed by heart puncture 24 hours previously. Note: Reticulocytes are larger than the mature red blood corpuscles. ($\times 1000$.)

Blood film (permanent preparation), vitally stained, from Case 5 (see table), in the relapse stage of pernicious anaemia. Note: Large reticululated megalocytes whose mean diameter is between 11μ and 15μ . ($\times 1000$.)

Blood film (permanent preparation), vitally stained, showing reticulocyte "crisis" following treatment with liver extract. Note: Various sizes and degrees of reticulation in the cells. ($\times 1600$.)

Price-Jones³ the error is certainly greater, since, in addition to errors due to the optical apparatus, the personal factor in drawing the outline of the cells and estimating the thickness of the pencil mark must be considered. Such investigators as Price-Jones and Ponder, who have studied the technique of the measurement of red blood corpuscles in great detail,

and 400 cells being measured from each film. In the case of cells which were not circular in shape the "diameter" was taken as the mean of the actual maximum and minimum diameters. Measurements were made at intervals of 1μ , and the cells classified accordingly—e.g., into a group whose diameter was greater than 6μ but less than 7μ ; greater than 7μ , but less than 8μ , &c. A cell whose diameter was exactly, say, 7μ was put into the $7-8\mu$ group, and so for

those of exactly 6μ , 8μ , 9μ , &c. In some cases measurements were made at intervals of 0.5μ , but it was found that this involved considerably more labour and did not, for the particular purpose in view, produce any better results. In the later work the films were projected directly on to the ground glass of a microphotographic apparatus and measured there in an exactly similar fashion, the possibility of drawing error being thus eliminated.

The Measurement of Reticulocytes.

1. *Following Hæmorrhage in Normal Persons and Animals.*—There appears to be no doubt that the first reticulated cells to appear in the circulation are larger than mature red blood corpuscles. A diminution in size rapidly occurs, so that many reticulated cells soon have the same diameter as mature red blood corpuscles. With the maturation of the cell a progressive loss of reticular substance occurs. (See Figs. 1 and 2.)

2. *Pernicious Anæmia in the Relapse Stage.*—An examination of vitally stained films of reticulocytes in the blood in the relapse stage, when the count was a million or less, showed that two kinds of reticulocytes were present: (a) Reticulated megalocytes, the largest cells seen, measuring from $9-13\mu$. (See Fig. 3.) (b) Reticulated normocytes from $8-9\mu$. The dividing line between reticulated normocytes and megalocytes is purely arbitrary. (See Figs. 1 and 2.)

3. *Pernicious Anæmia in the Remission Stage.*—As we have described,⁴ the therapeutic administration of liver and liver extract produces in a few days a stimulation of the bone-marrow with a consequent flooding of the circulation with reticulocytes. The majority of these cells are similar to the reticulocyte found in normal persons after hæmorrhage. While larger than mature red blood corpuscles, they are smaller than the reticulated megalocytes already

cells resulting from excessive stimulation of the bone-marrow; (b) normal cells from healthy bone-marrow; (c) large cells from abnormal portions of the marrow. It is obvious that since the small diameter of the microcytes counterbalances the large diameter of the megalocytes, the mean diameter of the cells in

FIG. 6.

Showing two types of secondary anaemia (Cases 7 and 9), compared with the normal.

FIG. 5.

Showing the effect of liver treatment on the diameters of red blood corpuscles in pernicious anaemia (Case 5).

described (Fig. 4). A small percentage of these latter cells are present until the count has reached between 2-3 millions.

The Measurement of Mature Red Blood Corpuscles.

(1) *Normal Persons.*—The table (Case 1) shows that 95 per cent. of the cells have a diameter between 7 and 9μ . The average mean diameter was 7.7μ and the coefficient of variation (index of anisocytosis) was 5.2.

(2) *Cases of Pernicious Anæmia in the Relapse Stage.*—Depending on the degree of anæmia, the diameter of the cells varied from 4.5 to 13μ . Three classes of cells appear to be present: (a) very small

pernicious anæmia will be only slightly greater than that of normal persons. In practice this variation is usually 1μ or less. On the other hand, the index of anisocytosis is two or three times as great. (See table, Cases 3, 4, and 5.)

(3) *In Cases of Pernicious Anæmia after Liver Treatment.*—As the number of red blood corpuscles increases a reduction of the number of the small and large cells takes place. When the count has reached 4 millions it is a matter of considerable difficulty to recognise the film as one from a case of pernicious anæmia. Measurement, however, clearly shows that the percentage of cells between 8 and 10μ is higher than that found in normal persons. The mean diameter and coefficient of anisocytosis are markedly reduced, but still greater than normal. (See Cases 4B, 5B.) Fig. 5 depicts the curves of a normal person and of a case of pernicious anæmia before and after treatment with liver. It is typical of several cases with a count of over 4 million red cells which the writers have measured. The shaded area denotes the excess of large cells over normal. The question arises, therefore: Does the blood in pernicious anæmia ever return completely to normal? Minot and Medearis⁷ claim that it does, and that the mean diameter may become even less than normal.

Five patients with counts of over 5 millions were examined, and it must be admitted that without measurement it would have been impossible to recognise the blood films as those of pernicious anæmia. Measurement, both by the Price-Jones and by the camera method, showed that from 5 to 15 per cent. of cells were still from 0.5 to 1μ bigger than those found in normal persons. (See Case 6.) The coefficient of anisocytosis had not returned to normal, although in one case the average mean diameter was less than that found in the blood of healthy persons.

These findings were fully supported by Price-Jones at the recent meeting of the Pathological Society in Edinburgh. The importance of these observations is that they clearly show that the disease is not permanently cured, but only temporarily improved. Hence cessation of treatment invariably results in a relapse.

The Measurement of Red Blood Corpuscles in Other Anæmias.

Before commencing this work the writers were under the impression that a secondary anæmia with a low colour-index was characterised both by a low hæmoglobin content and a small size of cell. Case 7 illustrates these points. A secondary anæmia, however, of a different type appears to be illustrated by Cases 9 and 10. Although the colour-index is low measurement of the red blood corpuscles reveals the fact that large types of cells are present (Fig. 6).

CASE 9.—Female, aged 50. Diagnosed as pernicious anæmia and treated with arsenic. Remission and great gain in weight. Six months later relapse; no response to arsenic. Blood count: red cells, 2,470,000; hæmoglobin, 30 per cent.; colour-index, 0.6. Death.

Post mortem: Gastric cancer and massive involvement of liver; red-currant-jelly appearance of bone-marrow; no metastases in the marrow. As judged by the presence of megalocytes the case could be diagnosed as pernicious anæmia. As judged by the colour-index and the post-mortem findings it was undoubtedly a case of secondary anæmia.

CASE 10.—Female, aged 32. Acute nephritis six years previously. At examination patient was bordering on uræmia. Percentage of non-protein nitrogen, 270 mg. Blood count: red cells, 1,540,000; hæmoglobin, 22; colour-index, 0.7. Treatment with liver extract produced 15 per cent. reticulocytes. Patient died five days later.

Two Types of Secondary Anæmia?

One of us (Davidson, 1928)* suggested that the essential feature in pernicious anæmia is a deficiency of some unknown substance necessary for the maturation of megaloblasts in the bone-marrow, while in secondary anæmia the essential feature is either hæmorrhage or the effect of toxins acting on the hæmatopoietic system. If this be so Cases 9 and 10 (see table and Fig. 6) combine the features of both conditions. Hence in Case 10 the response of the bone-marrow to the exhibition of liver extract shortly before death is of great interest. Most workers have found that the beneficial effects of liver therapy in secondary anæmias are inconstantly produced and are never quantitatively so marked as in pernicious anæmia; the writers agree with this in so far as it applies to such cases as 7, which failed to respond. It seems probable that benefit might be expected in cases similar to 9 and 10, since the presence of large red blood corpuscles is suggestive of a deficiency of the specific factor manufactured by the liver cells.

The writers believe that it would be a matter of considerable importance if two types of secondary anæmia could be shown to exist. In both a low colour-index due to deficiency of hæmoglobin is present. One type is characterised by a preponderance of small cells, while the other has a Price-Jones curve similar to that found in pernicious anæmia during the early part of the remission stage. (See charts.)

Liver therapy itself cannot remove the causal condition in secondary anæmia, but, by procuring the maturation of megaloblasts and normoblasts, it would diminish the number of abnormal red blood corpuscles entering the circulation and thus reduce the blood destruction which is proceeding in the reticulo-endothelial system.

MEDICO-LEGAL ASPECTS OF FRACTURES.*

By E. W. HEY GROVES, B.Sc., M.S. LOND.,
F.R.C.S. ENG..

PROFESSOR OF SURGERY IN THE UNIVERSITY OF BRISTOL;
SURGEON TO BRISTOL GENERAL HOSPITAL: VICE-
PRESIDENT OF THE ROYAL COLLEGE OF
SURGEONS OF ENGLAND.

THE problems presented by fractures of the long bones are as old as history and as new as the last written chapter of physical science. Six thousand years ago the wealthy athlete of Egypt had his fractured radius splinted by the mid-rib of a palm leaf, and meeting with an untimely death has bequeathed his limb to the Royal College of Surgeons in London. In that same College, the curator, Sir Arthur Keith, is every day investigating the mysteries of bone growth and bone repair under the influence of endocrines, agents of radio-activity, and the subtle interaction of biochemical forces.

But for the moment we are concerned less with the scientific aspects of fracture than the legal responsibility and liability of the fracture-mender. It would be interesting to speculate on the fate meted out to the practitioner of ancient Egypt who made a mess of his job. Possibly the incident ended on the banks of the Nile with a crocodile as a participator, but more probably the legal profession took part in the process of punishment and earned fees in the undoing of the doctor, a proceeding which their descendants have pursued ever since.

The liability of a medical practitioner to a charge of malpraxis is much greater when he is dealing with a simple external injury than when he is treating a patient suffering from an internal or obscure disease. The broken bone is just such a subject about which the general public have that little knowledge which is so dangerous. Not only is the maimed limb visible and palpable to the patient and his friends, but the disability from which he suffers is more or less obvious and permanent; and to these two facts is now added that he is generally in possession of X ray pictures upon which he places his own interpretation.

Injuries and Accusations.

Last year I was enabled by the courtesy of a legal friend to collect brief notes of 50 consecutive cases in which legal proceedings had been threatened or carried out against medical men for alleged negligence or malpraxis in the treatment of fractures. Classifying these according to the bone or region involved we have the following list:—

Clavicle	1	Femur, neck	11
Shoulder	9	" shaft	3
Elbow	3	Patella	1
Radius and ulna	4	Tibia	5
Wrist	5	Ankle	5
Digits	3		

In a paper in THE LANCET entitled Damages to Bones and Reputations,¹ I discussed these cases in some detail, and I will, therefore, only refer to some general inferences which may be drawn from them. The first and most glaring fact is that most of them turn upon X ray evidence or its absence. One wonders very much whether litigation ever took place about fractures before Röntgen's discovery. In the present series one finds that in no less than 90 per cent. of the cases the radiogram was the dominating factor. In the majority the fact that there had been a fracture at all had been overlooked. Of this the typical and commonest example is the fracture of the neck of the femur, which often occurs with so little violence that neither patient nor doctor can imagine that a big bone has been broken. At first there is very little displacement and practically no deformity. The serenity of the convalescence is

* An address delivered before the Medical Society of London on Nov. 12th. ¹ THE LANCET, 1928, i., 167.

usually disturbed either by the advent of the masseuse who with vigorous exercises quickly demonstrates pain and crepitus, or by the first attempt by the patient to walk, when the weight of the body quickly causes displacement, while the pain and weakness many weeks after the accident point to a grave injury and lead to the belated X ray examination. In another much less common train of circumstances a radiogram is taken at an early date; but it shows so little displacement that the gravity of the condition is minimised, it is thought that the bone is only cracked, or that there is impaction. Later on the masseuse or the body-weight play their part, and full displacement is made manifest.

In another group of cases the nature of the main injury is obvious, so obvious that a radiogram seems superfluous waste of time. But in the course of time, when the chief deformity has been corrected, but pain persists and function refuses to return, then radiological examination is done and some complicating bone injury is discovered. Very often the earlier recognition of this complication would not have had the slightest influence on the early treatment; but the damning fact remains, and is made use of by a querulous patient or by a litigious adviser that the full nature of the injury was not discovered at the time of the accident. Examples of this kind of case are afforded by injuries of the shoulder or wrist. In the former an obvious dislocation may be accompanied by a fracture of the tuberosity of the humerus or of the glenoid fossa. In the latter a Colles's fracture may also have a fracture or dislocation of one of the carpal bones. Or, again, the fracture of the shaft of one of the long bones may be so obvious that immediate setting and splinting are carried out and the patient is restored to comfort. The condition is not examined or disturbed for several weeks and then sooner or later as a matter of routine or because progress is unsatisfactory the inevitable radiogram is taken and malunion is discovered, usually a lateral displacement which looks dreadful to the patient and his friends. Perhaps then operative treatment has to be undertaken and the doctor who first saw the case is expected to pay for this, and he will be lucky if he has not also to pay a substantial solatium to the patient together with fees for litigation.

Yet another type of case is that of a fracture which is treated on ordinary conservative lines, and then for one reason or another falls into the hands of another practitioner. The latter performs an operation and finds some condition which it is suggested shows negligence on the part of the original medical attendant. No radiogram had been taken by the latter, and therefore there is no way of refuting the charge.

For example, a patient with a fractured clavicle, having been treated on the ordinary lines but not X rayed, was transferred to the charge of a second practitioner, who declared immediate operative treatment to be necessary, and further stated that at the operation he had found a splinter of bone threatening the integrity of the vessels and nerves. Needless to say, the splinter of bone was not produced, and the case went against the defendant, chiefly because he had no radiographic evidence to support his contention that the injury was of a simple character which did not require any operative treatment.

I think after this simple recital it ought not to be necessary to say another word in support of the contention that injuries to the bones and joints must be subjected to radiographic examination at the earliest possible moment. Of course there are certain difficulties, such as that of transport or expense, which will have to be met, but in the great majority of cases where trouble has resulted the difficulty of getting the X rays was not the result of circumstances but rather of the deliberately expressed opinion of the medical man concerned, that X rays were not necessary.

A Series of Medico-legal Cases.

At this point I should like to summarise all the medico-legal cases I have examined and to classify

them according to the chief factor in bringing the charge, expressing the number of cases in percentages.

Absence of X rays—						
Diagnosis missed	..	..	..	..	..	53
Some complication overlooked	..	..	..	..	..	13
Malunion not recognised	..	..	..	..	..	12
Allegation by hostile practitioner could not be refuted	..	..	..	..	..	4
						99
Hostile action based on adverse criticism by another practitioner		..	..	..	..	10

From this table it will be seen that in addition to the 90 per cent. of cases which turned upon the absence of radiographic evidence there remains about 10 per cent. in which it was the hostile criticism of another practitioner which suggested or supported the idea of an action for negligence. A typical case of this sort is one of delayed union in the leg bones in which after six or eight weeks' treatment by splints or plaster the fracture is found to be ununited and a second opinion is sought. At this stage some fresh treatment is advised, whether by manipulation, an ambulatory splint, or operation.

Unfortunately, the practitioner who carries out this treatment is often not content with having secured the patient, but allows himself to express some hostile criticism, or at any rate assents to an opinion expressed by the patient, hostile to the first doctor. This opinion then actually forms the basis of the action for negligence. This factor of one medical man criticising or condemning another is in reality very much more important than the figure of 10 per cent. would indicate. The great majority of all the other 90 per cent. of the cases, although they may turn upon the neglect of X rays, are nevertheless supported by the criticism of one medical man about the conduct of another. I will return to this point again later at the conclusion of my address.

Tyndall v. Alcock.

A case has recently occurred which in many respects marks a new departure in actions against medical men relating to the treatment of fractures, and which I think therefore merits some detailed examination.

Phyllis Tyndall, a girl of 9 years of age, fell on her left elbow at Newent on July 8th, 1926. She was taken by her mother and a friend in a motor-car to Gloucester, a distance of about 10 miles, Dr. Alcock, one of the surgeons to the Gloucester Infirmary, being notified by telephone of the accident.

When the car arrived at his house he saw at once that the injury was of a serious nature. The arm had been held straight out without any splinting or bandage and was by this time considerably swollen round the elbow. He therefore took her straight to the consulting-rooms of an X ray specialist, where the arm was X rayed, showing a supracondylar fracture of the humerus. Under an anæsthetic the arm was manipulated so as to reduce the backward displacement of the lower fragment and the elbow fully flexed in order to retain this reduction. The child was still on the X ray couch and the radiologist examined the arm with the fluorescent screen and told Dr. Alcock that the reduction was satisfactory.

In order to have a record of this condition, a film was taken; but for some reason which I do not understand, instead of taking the picture with the arm lying on the chest, the limb was rotated outwards so that the hand came to lie outside the shoulder. The picture having been taken the hand was brought back so as to lie on the front of the chest on the inner side of the shoulder. It was this radiogram which appeared to be the chief rock upon which Dr. Alcock's case foundered, but I will complete the history of the case before commenting upon it. Dr. Alcock took the child himself in his car to a nursing home and he kept her under his own supervision for some days and for a further period of several weeks at the Gloucester Infirmary, to which institution she was transferred.

The day after the accident it was evident that the circulation of the limb had been seriously interfered with, and within two or three days the position of acute flexion was released and the arm brought down to a right angle. Subsequently it became quite evident that the child had typical ischæmic contracture, together with almost complete fixation at the elbow-joint. The case was tried at the Bristol Assizes in December, 1927, and Dr. Alcock was found guilty of negligence and had to pay £2000 as damages for the injury suffered by the child together with £150 for special expenses incurred by the mother in travelling to and fro.

As I have said, it seems to me that this case marks so grave a departure from all other precedents that we ought to examine it with great care to understand its lessons and, if possible, to suggest some safeguard by which the repetition of such injustice may be prevented. Dr. Alcock was found guilty of negligence, and yet nothing could be more plain than in the ordinary meaning of the term there was never a less negligently treated case than that of Phyllis Tyndall by Dr. Alcock. He met the child at his own doorstep, he took her straight to the X ray specialist, he had her anaesthetised at once, he took a radiogram before the treatment and after, he had another colleague in consultation, he took the child to a nursing home, and he gave her sedulous attention. The treatment he carried out was that laid down as the standard method by current text-books on surgery. I am told that the term negligence is intended to cover a want of ordinary skill, and that this was really what was meant by the verdict against Dr. Alcock. It is quite certain that the jury felt themselves in a difficulty; they came back more than once to consult the judge, and suggested to him that they did not think that Dr. Alcock had been negligent, but he had not set the fracture properly. The judge, however, insisted on a clear-cut verdict either for the plaintiff or defendant, so that the jury found themselves obliged to bring in the verdict they did in order to secure some monetary compensation for the victim of this unfortunate accident. In matters of this sort it is very much easier to attack than to defend, and the attacking counsel lost no opportunity of throwing discredit upon Dr. Alcock's conduct of the case. There was a good deal of conflict of evidence by the various nurses who had seen the child as to the exact way the arm was bandaged and the exact date on which the bandages were released: but considering the case had occurred more than 12 months before the date of the trial such conflicting evidence ought not to have been held to discredit Dr. Alcock's statement.

The most astonishing feature of the trial was the part played by the X ray evidence and the relation alleged to exist between the fracture and the ischaemic contracture. The X ray film taken directly after the manipulation ought never to have been admitted as evidence at all, because it did not represent the position in which the arm was actually fixed against the side. But actually this picture was the most important evidence relied upon by the plaintiff. It was contended that it showed that the fracture had not been properly set, and the jury were easily convinced on this point, because the fractured pieces of bone are evidently not in close apposition. The question as to whether the fracture was set or not had nothing whatever to do with the main point at issue—namely, the occurrence of ischaemia. The actual interference with the circulation was, of course, caused by the arm being too acutely flexed at a time when there was progressive exudation into the tissues of the elbow. At the time when the arm was put up the pulse was not affected, but it disappeared the next day, and then the acute flexion was relieved. If this case had been presented in this light then the charge against Dr. Alcock would amount merely to this: that he put up the arm in the correct way, but either with too much tension at the time or without enough margin of safety to allow for increased tension arising in the tissues. In other words, he was perfectly right to put the arm up in acute flexion according to the standard text-book advice, but that the flexion was too acute. I think it is fairly clear that if the charge had been made in this way the case would have gone very differently. It was merely an error of judgment committed by a careful man who sought every possible assistance and followed out a standard method of treatment.

The plaintiff's counsel chose to go upon something much more definite than this: "a perfectly simple fracture" and X ray evidence that this perfectly simple fracture had not been accurately set. This was the main line of the attack upon Dr. Alcock which resulted in such a surprising verdict.

The Policy of Delay.

Quite apart from one's natural indignation at the injustice done to a careful and conscientious colleague, there arises the serious reflection that a verdict of this kind does so much harm to the conduct of surgical practice. Any man now who is asked to treat a fracture has a right to ask, "Why should I undertake this work which can only earn for me a few guineas and which may make me liable not only to a fine of thousands of pounds against which I can protect myself by the insurance of a defence society, but also to the harassing anxiety of a public trial in which a jury will be asked to decide whether I am a fool or a knave?" It is quite certain that a good many men will have nothing to do with a fracture because of some such line of argument as I have sketched above. But what is still more common and, in fact, is becoming an everyday occurrence, is for medical practitioners to see these cases and to decline to commit themselves to any active treatment; the limb is temporarily immobilised and active treatment is postponed until further opinion can be obtained or until a specialist will take over the responsibility. Such common injuries as Pott's fracture or Colles's fracture or this very thing we have been considering, fracture of the lower end of the humerus, a cautious practitioner will not touch in the first place. He ties up the limb and waits, first for the X rays and then for a consultant, which, of course, means that the period at which easy reduction could have been undertaken has passed by. This policy may be very good for the consultant, but it is certainly very bad for the community; nevertheless, it will, I think, be the inevitable result of such a decision as that made in the Tyndall and Alcock case.

Suggested Safeguards.

In conclusion, I would like to ask the question as to whether any practical suggestions might be made in order to protect the medical man from unjust charges and to secure for the community in cases of accident the willing service of medical men. There are three possibilities of this nature:—

1. That when a doctor is asked to attend an accident case he should ask the patient or the guardians to sign a declaration indemnifying the doctor in case his treatment does not produce a good result. This suggestion is open to many objections. In the first place, the great majority of medical men would never dream of taking this precaution. In the second place, it would be very difficult to draw up an indemnity form which would be held by any law court to be valid.

2. That steps should be taken to prevent any medical man giving evidence against a colleague without some preliminary consultation. It seems to me that this should not only be laid down as an ethical principle, but that it might very well be embodied in the conditions upon which a diploma is given to a newly qualified medical man. In principle the idea I am striving to suggest is quite simple, but it might be difficult to give it legal phraseology. The second stage in every medico-legal action, or sometimes it is the first stage, consists in one medical man accusing another of ignorance, incompetence, or negligence. He may not in the first place formulate the action, but in point of fact he is asked whether he will support it. I am not suggesting that he should refuse outright to express an opinion, but that he should insist on seeing the accused medical man and hearing from him his own account of the circumstances. In serious cases where the action cannot be averted it might be well if a third medical man of eminent position were invited to arbitrate as between the accused and the accuser. I am quite confident that in a large number of cases procedure of this kind would lead to a settling of the disputed case out of court, and it would at any rate prevent the unhappy spectacle of one medical man, who has criticised a colleague, being put into the witness-box and having his opinion distorted and exaggerated by an adroit counsel for the undoing of his brother. The great

advantage of this reform is that it lies wholly in the hands of our own profession, and we should not have to ask the legal profession to give us help and advice in avoiding litigation.

3. That a medical expert be appointed to act as an assessor or assistant to the judge in High Court cases involving charges against medical men based upon technical matters of practice. There is ample precedent for some suggestion of this kind. It is a system which I am told is carried out in France. The county court judges in this country have the assistance of a medical referee in cases coming under the Workmen's Compensation Act, and also, I believe, in the Admiralty Court the judge is assisted by a shipping expert in technical matters. The great difficulty that I see in this suggestion is how to bring it about. Probably it would be stoutly opposed by the legal profession, and it would be difficult to claim any public support for the reform because its mere formulation would be considered to be only in the interests of the medical profession. But I suppose there is very little likelihood of any reform of this kind being introduced at present. Medical opinion would have to be educated and united, whilst legal opposition and obstruction would have to be fought. In the meantime I am sure it is quite wrong for practitioners to be intimidated by one or two exceptional acts of injustice. Fortunately, the great majority of patients recognise and are grateful for the bona fide labour of the doctor on their behalf, and would never dream of vindictive action against him, if his treatment is followed by a bad result. Work carefully done, adequate insurance against risks effected, and a dependence upon his colleagues to act towards him as a brother—these must remain the factors of safety and peace of mind for the medical man who has to undertake the treatment of fractures.

THE SYNERGISTIC ACTION OF ŒSTRIN AND PITUITARY EXTRACT ON THE ISOLATED UTERUS.

BY ALECK W. BOURNE, M.B. CAMB.,
F.R.C.S. ENG.,

OBSTETRIC SURGEON, OUT-PATIENTS, ST. MARY'S HOSPITAL; SENIOR
OBSTETRIC SURGEON, QUEEN CHARLOTTE'S HOSPITAL;
SURGEON, OUT-PATIENTS, SAMARITAN HOSPITAL;

AND

J. H. BURN, M.D. CAMB.,

DIRECTOR OF THE PHARMACOLOGICAL LABORATORIES OF THE
PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.

(From the Pharmacological Laboratory of the Pharmaceutical
Society.)

ALTHOUGH it is now five years since Allen and Doisy first described the preparation of an œstrus-producing hormone, our knowledge of the part it plays in human reproduction is still meagre. Thanks to the researches of Parkes¹ we know that the view that the follicles of the ovary are the principal structures which produce it is incorrect, and that there is no justification for the name "follicular hormone." That it plays some part in pregnancy is evident from the presence of large amounts (a) in the urine towards the end of pregnancy, and (b) in the placenta.

A curious observation, which suggests that œstrin may have a relation to the occurrence of parturition, is that in some animals—the guinea-pig, for example—the phenomena of œstrus, absent during pregnancy, are seen immediately after parturition is complete, and are then again absent until the termination of lactation. The occurrence suggests that at the time

of parturition a sudden liberation of œstrin takes place. Having this in mind we began a clinical investigation of the effect of œstrin on the human uterus in labour. This work is not yet complete, but we were able to record some observations compatible with the view that œstrin, in a water-soluble form, when previously injected, enhanced the efficiency of subsequent injections of pituitary extract in maintaining uterine contractions to the end of labour. These observations, though in themselves insufficient to be conclusive, prompted us to see whether, in the laboratory, any synergism between œstrin and pituitary extract could be demonstrated on the isolated uterus.

Some experiments at first sight of this nature have been described by Brouha and Simonnet.² They injected guinea-pigs with an extract of follicular fluid in olive oil, and later killed the animals and tested the effect of pituitary extract on the isolated uterus suspended in a bath. They stated that as a result of the injections the uterus muscle contracted more promptly and maintained a prolonged rhythm when pituitary extract was added to the bath. There is, however, much variation in the response to pituitary extract of the uterine horns of different guinea-pigs, and, before they could establish the conclusion stated, it would have been necessary for these authors to have compared a large series of injected and uninjected animals. This they did not do. Moreover, had they done this, there would have been nothing new or surprising in the properly established conclusion. It has always been the bugbear of those whose duties involve the standardisation of pituitary extract on the isolated guinea-pig uterus that the muscle, if removed from the animal during or near œstrus, is so unusually sensitive to the stimulant action of pituitary extract that a proper comparison of two extracts cannot be made. It was to be expected that an artificially induced œstrus would be attended by a similar hypersensitiveness of the isolated muscle.

Material Used.

Our own experiments have been carried out with two samples of the water-soluble œstrin which were very kindly presented to us by Prof. E. Laqueur, of Amsterdam. The preparation is sold on the continent under the name of Menformon. They were tested for their ability to produce œstrus in ovariectomised rats in this laboratory, and the dosage given hereafter is the dosage as we determined it. We define the unit as that dose which, given to each rat as a single injection, produces œstrus in 10 out of 20 ovariectomised rats.

Procedure.

The procedure was as follows:—

A virgin female guinea-pig, weighing 180–200 g., was killed by a blow on the head, when its throat was cut and blood allowed to drain out. One horn of the uterus was suspended in a bath of the pattern described by Burn and Dale.³ The Ringer's solution was of the composition recommended by these workers. The writing lever was

FIG. 1A.

suitably weighted, and when the muscle was properly relaxed, a dose of pituitary extract was determined just large enough to produce a very small contraction of the muscle. In Fig. 1A there is shown (on the left) a small contraction produced by 0.01 units of pituitary extract added to a bath of 100 c.cm. At the mark R on the tracing, the Ringer's solution was changed so as to remove the pituitary extract from the bath. A dose of 0.05 units of oestrin was then added to the bath and allowed to remain during six minutes. At the end of this time the same dose of pituitary extract was again added, but now the contraction was very much greater than that previously recorded. When the muscle began to relax, the Ringer's solution in the bath was again changed to remove both oestrin and pituitary extract. After complete relaxation it was again observed that the pituitary extract alone produced only the very small contraction first recorded.

The isolated uterus of the guinea-pig is well known to display spontaneous changes in the size of the contractile response to a given stimulus; the fact, however, of having the same small response to pituitary extract after, as well as before, the big contraction in the presence of oestrin, is good evidence that a spontaneous change did not take place. This evidence became conclusive when in a series of experiments the same phenomenon was regularly observed.

A convincing result is that shown in Fig. 2 in which the muscle was taken from a young guinea-pig of 180 g. weight. The muscle was unusually insensitive, so that a dose of 0.05 units of pituitary extract produced only a trace of contraction. In the presence of 0.5 units of oestrin the

how far it was due to other materials accidentally present in the preparation of oestrin used. It is known, for example, that solutions containing protein have this effect; since, however, the water-soluble preparation of Laqueur contains only traces of protein, it was unlikely that the effect was due to their presence. Unfortunately there is no simple means of destroying the oestrin hormone, so that it was impossible to carry out experiments with an inactivated sample. There remained the possibility, if the effect were specific, that the increased sensitive-

FIG. 3.

Shows that oestrin itself will cause the contraction of a spontaneously active uterus.

FIG. 2.

A similar picture to that in the upper part of Fig. 1. The uterus in this experiment was very insensitive and the augmentation of the pituitary effect by the oestrin is therefore the more convincingly shown.

effect of the same dose of pituitary extract was very much greater, as shown in the figure.

Specificity of Effect.

It remained to discover how far the increased sensitiveness of the muscle to pituitary extract was due to the specific oestrin-producing principle, and

FIG. 1B.

Fig. 1A and 1B. Tracings read left to right. P.E., pituitary extract; H., histamine; R., release of Ringer's solution. Note the small test dose of 0.01 units P.E. at the beginning of the tracing in Fig. 1A, and the large response to the same dose when 0.05 units oestrin are present in the bath. Fig. 1B shows the absence of any synergism between histamine and oestrin.

ness to pituitary extract would be found not to be accompanied by an increased sensitiveness to other uterine stimulants. It is known, from the characteristics of the contractile response, that the mechanism differs in some way according as the contraction is evoked by potassium chloride, histamine, or pituitary extract. Was it the case that whereas oestrin made the uterus more sensitive to the stimulus of pituitary extract, it had little or no effect on the response to the stimulus of histamine? We did not expect that any such difference would be found. If the contractile mechanism were rendered easier to set in motion, we thought that this greater readiness to contract would be displayed to all stimuli. The tracing in Fig. 1B shows that we were wrong, and that oestrin usually has no effect on the response to histamine under conditions in which it augments the response to pituitary extract. In other cases we obtained a slight augmentation of the histamine response.

We are of opinion that the absence of any synergism between histamine and the solution of oestrin used is evidence that the active constituent in the solution of oestrin is the oestrin itself. We find it difficult to suppose that a non-specific factor, such as traces of protein material, would augment the stimulant action of pituitary extract, but not that of histamine. Further, the fact that the relationship is specific inclines us to the view that the phenomenon is one

of physiological importance, though only clinical investigation can decide whether it can be given a therapeutic application.

It should be pointed out that œstrin itself, in the water-soluble form, will, in sufficient dose, cause a contraction of a spontaneously active uterus (Fig. 3). It is, however, in a quiescent muscle, which is unresponsive even to pituitary extract, that the synergistic action is most convincingly seen.

Mechanism of Parturition.

Dr. A. S. Parkes has pointed out to us that our observation agrees very well with the recent work of Knaus.⁴ This worker has studied the sensitiveness of uterine muscle during pregnancy to pituitary extract by a method which obviates the effect due to the presence of the foetal sacs. He has found that in early pregnancy the sensitiveness is very low, but that towards the end it becomes much greater; he has reason to associate the diminished sensitiveness with the activity of the corpus luteum.

As Parkes⁵ has recently pointed out, there is now an alternative hypothesis to that of Dixon and Marshall⁶ to account for the onset of parturition. Dixon and Marshall suggested that an ovarian hormone stimulated an output of pituitary secretion from a gland which had been resting during pregnancy. Now we need no longer consider that the pituitary secretion changes in amount from time to time; it is sufficient to suppose that during pregnancy the power of this secretion to stimulate the uterus is depressed by the corpus luteum, while on the decay of the corpus luteum at the end of pregnancy the sensitiveness of the uterus to pituitary extract is enhanced by the overriding influence of œstrin.

Clinical and Laboratory Notes.

A CASE OF PLURIGLANDULAR SYNDROME: "DIABETES OF BEARDED WOMEN."

BY W. HURST BROWN, B.M. OXF.,

ASSISTANT CHEMICAL PATHOLOGIST, ST. MARY'S HOSPITAL, LONDON.

IN 1921 Achard and Thiers¹ described a pluriglandular syndrome in women which, because of its striking clinical picture of virilism, or "hirsutisme," linked to glycosuria, they termed "le diabète des femmes à barbe." They mentioned six characteristic symptoms, the first three being the cardinal signs of "hirsutisme" (Apert),² while the last three were inconstant: 1. Hairs on the face (the latter being coarsely plethoric and masculine in type), with partial baldness, especially of the frontal region. 2. Disturbed genital functions. 3. Obesity, usually of the trunk, the limbs often being comparatively thin. 4. High blood pressure. 5. Cutaneous striæ (striæ atrophicæ or striæ cutis distensæ). 6. Glycosuria or lowered carbohydrate tolerance.

Langdon Brown³ described a case which, he said, apparently belonged, together with one recorded by Parkes Weber, to this particular type of virilism. In Parkes Weber's paper⁴ details were given of three similar patients, observed by Anderson, Turney, and Cushing, which although they did not exhibit glycosuria, in other respects closely resembled the case of Langdon Brown and Parkes Weber. As so few descriptions are found in the literature, the following case seems worth recording:—

An unmarried woman, housekeeper, aged 45, was admitted to the Medical Unit of St. Mary's Hospital on Nov. 1st,

1927. She complained of (a) excessive thirst; (b) increasing disinclination for food other than fruit; (c) weakness and numbness of the legs; (d) blurring of the vision; and (e) "a sinking sensation in the pit of the stomach with a feeling of blood rushing round the neck and chest." Apart from a tendency to stoutness since puberty she had always been alert, energetic, and in excellent health, until 1927 when she began to suffer from menorrhagia. While convalescent from an operation for hysterectomy in September, 1927, she was confined to bed for six weeks with thrombosis of the left long saphenous vein. Both she and her relatives dated the onset of her present complaint from the time of the operation.

The face was florid and pigmented with purpuric spots on the nose and cheeks. The breasts and chest were deeply pigmented. Obesity was marked, particularly of the back of the neck, arms, breasts, abdomen, and thighs; body-weight, 12 st. 8 lb. The legs were œdematous, the skin rough, scaly, and dry, with hyperkeratosis of the soles of the feet. The eyes were slightly prominent and the vision blurred, but the fundi were normal and there was no hemianopia. The mentality was dull and somewhat childish, the reflexes sluggish, and a fine tremor was apparent on extending the fingers. No enlargement of the heart, spleen, or liver could be detected.

The urine showed albumin, pus, traces of blood, sugar (7.2 per cent.), and diacetic acid (trace). The reaction to insulin was irregular; at one time she had 1.8 per cent. sugar in the urine on diet and 70 units of insulin, while later she was sugar-free on a diet of 1595 calories without insulin. A blood-sugar curve showed a resting value of 370 mg., rising to 413 mg. one hour after 50 g. of glucose were given, and falling to 360 mg. per 100 c.cm. in two hours. Blood pressure: systolic, 240; diastolic, 160. On admission the red cell count was 5,720,000 and the white cell count 15,600, but in one month these fell within normal limits. The blood volume, determined by the "vital red" method, was found to be less than normal—one-fourteenth (7.3 per cent.) of the body-weight, or 69 c.cm. of blood per kilo of body-weight with a hematocrit value of 54 per cent. The blood-urea was 31 mg. per 100 c.cm. The quantity of blood cholesterol was too minute to estimate. Microscopic examination showed the capillaries around the nail beds to be less numerous than normal and of distorted and abnormal outline. No enlargement of the pituitary fossa was apparent in X ray films. No evidence of sepsis was found in tonsils, sinuses, or antra. The basal metabolic rate was plus 20.

The patient developed an acute parotitis and one septic tooth was removed. The traces of blood and albumin persisted in the urine. Increasing drowsiness and mental torpor were accompanied by asthenia and painful cramps of the legs and back. She became almost bald on the frontal region, and while hair was shed from the head, hirsuties appeared on the chin and upper lip. The face and breasts (areolæ) became more deeply pigmented and the purpuric spots more numerous and widely distributed. She bruised very easily, but at no time did she exhibit definite cutaneous striæ. She was diagnosed as a case of pluriglandular defect, but the administration of various combinations of glandular and polyglandular preparations produced no improvement. During the last two months her pulse-rate was rapid (96–112), and her temperature, which had been normal for a month, began to rise in the later stages, when an icteric tinge was noticeable. After being in hospital for five months she died from heart failure and nephritis on March 2nd, 1928.

Post-mortem Examination.

Autopsy performed by Dr. W. D. Newcomb 54 hours after death revealed the following conditions. Heart: fatty degeneration and great hypertrophy (weight 550 g.). Lungs: one typical oat-celled carcinoma 1 cm. in diameter. Liver: central congestion and necrosis of lobules with peripheral fatty change. Kidneys: purulent infiltration of both cortices and medullæ. Spleen: slightly enlarged and congested; Malpighian bodies small. Bone-marrow: right femur showed hyperplasia, upper 35 cm. red, lower 5 cm. fatty. Microscopic examination showed that half of the red marrow was fatty and that erythro- and leucoblastic elements were present in about equal numbers, while megakaryocytes were unusually small and numerous.

Choroid plexus: bilateral psammomata. Pineal body: normal. Pituitary gland: enlarged, and much colloid was found in large vesicles in the intermediate lobe. Thyroid: colloid adenomatous hyperplasia. Thymus: replaced by fat.

Pancreas: islets of Langerhans apparently normal (there was much fatty infiltration and post-mortem degeneration throughout the gland).

Suprarenals: enlarged. The cortices contained very little lipid and there was a large amount of iron-free brown pigment in the zona reticulata. The medullæ were larger than normal and showed patchy perivascular lymphocytic infiltration.

Ovaries: enlarged and fibrosed, containing a few ill-developed Graafian follicles. The capsules were thick and fibrous and exhibited numerous corpora albicantia.

It appears from this and previously reported cases of "diabetes of bearded women," that in addition to the six characteristic signs of the condition (vide supra), the following three points may be of considerable diagnostic importance: 1. A minor degree of double exophthalmos. 2. An increased basal metabolic rate. 3. In the early stages a definite, although mild and transient, polycythæmia.

Exophthalmos of slight degree with optic neuritis was reported in the cases of Cushing, Anderson, and Parkes Weber. Turney's case showed retinal changes, three-fourths of the right disc being surrounded by a white subretinal exudation, and Parkes Weber remarked upon the presence of white foci around the discs of his case. In the case here described no retinal changes were associated with the exophthalmos.

Polycythæmia was reported by Turney, and Parkes Weber's case apparently had an abnormally high erythrocyte count in the earlier stages.³ In the light of these facts it is possible that the figure of 5,300,000 red cells per c.mm., recorded in the cases of Cushing and Langdon Brown, may have indicated an earlier polycythæmia.

The basal metabolic rate has been recorded in only two of the above-mentioned cases. Parkes Weber's case had a B.M.R. of plus 20, and Langdon Brown recorded a B.M.R. of plus 15. He remarks that this result is interesting in conjunction with the marked obesity.

I have not found any record of the microscopy of the capillaries in other reported cases, but the findings in the present case suggest that the remarkably poor definition and distortion of the outlines of these vessels may well be the explanation of the bruising and petechial hæmorrhages which have been features of almost all the cases recorded.

I have to thank Prof. F. Langmead for his kindness in permitting me to report the case when I was house physician to the Medical Unit.

NOTE ON A

URETHRAL CALCULUS OF UNUSUAL SIZE.

By H. R. B. HULL, M.R.C.S. ENG.,
AND

R. J. G. PARNELL, M.R.C.S. ENG.

SURGEON-COMMANDERS, R.N.; UROLOGICAL SPECIALISTS,
MEDITERRANEAN FLEET.

URETHRAL calculi are usually secondary, that is to say, they do not originate in the urethra, but from small calculi passed into the urethra from the ureter, bladder, or prostate. Primary stones are rare, seldom attain a large size, and are with few exceptions single. Whatever their origin, their retention in the urethra without symptoms is most exceptional. The stone in this case was very large, and there were certain features which seem to us worthy of record.

The patient, a stoker, who was in training for the Fleet Marathon Race and had run six miles a few days before, sought advice on account of a thin mucoid gleet. There was a history of penicthra seven months previously, complicated by epididymo-vasitis. Whilst palpating Cowper's glands, a hard spindle-shaped body was found lying in the long axis of the bulbous urethra, apparently within its lumen. The patient was unaware of its presence. His health during the past four months had been excellent, and there was no history of impaction.

Attempts at catheterisation were unsuccessful, owing to the small calibre of the *fovea navicularis*. Operation was performed on board the hospital ship *Malva*. A sound was passed after anaesthesia. This showed that the foreign body was a stone in the bulb as it moved through a perineal fistula was easily effected. The base of the bulb was of normal thickness. The divided layers were sutured over a

catheter, which was removed on the fourth day. Slight leakage of urine occurred for a week. The wound was soundly healed on the nineteenth day after operation.

The stone weighed 163 grains; its length was $1\frac{1}{2}$ in. and its greatest diameters were $\frac{3}{4}$ in. and $\frac{5}{8}$ in. On section it had a hard outer shell, covering a laminated phosphatic core. Owing to an error in gauging the focal distance of the camera, the photograph here reproduced is a little smaller than the actual size. The raised facet shown in the photograph was lying ventrally over the openings of Cowper's glands.

That there was considerable distension of the bulb was shown by the fact that, during convalescence, the patient had to press the perineum over the bulb after micturition in order to avoid dribbling of urine. When the tissues contract, as they will in the course of time, urination should become normal.

To adjudicate whether the stone was primary or secondary is a matter of some difficulty. The history suggests that it was primary.

Calculus removed from the bulb of the urethra (slightly less than actual size).

A NOTE ON THE

PAIN SENSE OF THE PARIETAL PLEURA.

By A. I. G. McLAUGHLIN, M.B., CH.M. SYD.,
ASSISTANT MEDICAL OFFICER, TUBERCULOSIS DEPARTMENT,
ST. THOMAS'S HOSPITAL, LONDON.

IN a recent communication to *THE LANCET*¹ on the Mechanism and Elements of Pleural Pain, I stated that it is generally accepted that the visceral pleura is insensitive, that the costal parietal pleura is supplied with sensory nerves from the intercostals, and that certain types of irritation or stimulus to the membrane are experienced by the patient as definitely localised pain. I find, however, that some authorities, influenced largely by the observations of Sir James Mackenzie, still state that the parietal pleura has no pain sense. Samson Wright,² for instance, says:—

"Irritation of the pleura reflexly produces coughing, but no pain sensibility is present in the pleura. This statement seems greatly at variance with the well-known severe pain of pleural inflammation. Neither scraping nor penetration of the parietal pleura produces pain, as can be well shown when resections of the ribs are carried out under local anaesthesia. The nerve-supply to the pleura is not known; cerebro-spinal nerve-fibres do not appear to have been traced into, nor do nerve plexuses lie in the surrounding connective tissue."

On the other hand, such writers as Behan³ and Schmidt⁴ are of the opinion that the parietal pleura is definitely sensitive. Behan states that the parietal pleura is innervated by the intercostal, sympathetic, and vagus nerves, and the visceral by the vagus and sympathetic.

Up to the present little anatomical evidence has been adduced to support the theory that the parietal pleura is supplied from the intercostal nerves. Prof. F. G. Parsons,⁵ however, in a recent dissection of a part of the chest wall, showed quite clearly branches from the intercostals going to the parietal pleura. A. S. Dogiel⁶ demonstrated the presence of sensory end-bulbs in the human parietal pleura, and M. J. King,⁷ quoted by H. A. Bray,⁸ found them in the parietal pleura of the rat, calf, rabbit, and guinea-pig. Bray also quotes the observations of S. V. Sewell⁹ who noted that in operations under local anaesthesia manipulation of the non-anaesthetised parietal pleura evoked exquisite pain. The important experimental and clinical work of J. A. Capps¹⁰ on pleural pain showed very clearly that mechanical irritation of the inner surface of the costal parietal pleura nearly

always produced sharp and accurately localised pain, and that the pain sense was more marked anteriorly and laterally than in the posterior part of the membrane.

My own observations during the past five years have led me to the conclusion that the parietal pleura is richly endowed with pain sense. On the many occasions when I have been carrying out exploratory puncture of the chest, artificial pneumothorax, or aspiration of pleural fluid, I have paid particular attention to this point, and I have found that in nearly every case the parietal pleura is extremely sensitive, and gives rise to definitely localised pain when a needle passes through it. The needle in passing through the chest wall evokes pain in only three structures—the skin, the rib periosteum (if it should be touched), and the parietal pleura. The intercostal muscles and other structures are apparently insensitive, at least, to the stimulus set up by the needle. The patient describes the skin pain as an "ordinary" sharp pain, whereas the pleural pain is likened to a severe toothache or "neuralgia." In any case the patient, if questioned, has no doubt that there is a remarkable difference between the two pains. The intensity of the pain varies, of course, with the patient's temperament, the state of the general health, with the sharpness and size of the needle, and with the condition of the pleura—i.e., the pain is more intense in the presence of acute or subacute pleurisy than if the pleura is normal. If the pleura is not anaesthetised pain in some degree will be evoked by the passage of a needle in almost every case. When a thin and very sharp needle is used little pain is experienced, but a large and comparatively blunt needle evokes a considerable degree of pain. When a blunt needle is used a good deal of pressure has to be exerted to force the needle through the pleura, so that tension is set up at right angles to the plane of the membrane. A very sharp needle passes through with a minimum amount of resistance and produces little or no tension in the membrane. These facts suggest very strongly that the chief stimulus necessary to evoke pleural pain is tension or stretching.

It might be argued, and with some justification, that the pain arises when the needle is passing through the layer of connective tissue overlying the parietal pleura. That this is not so can be proved, to my satisfaction at least, by putting a needle attached to a syringe containing fluid through the chest wall when a pneumothorax is present. When the point of the needle is in the pneumothorax cavity bubbles of air can be withdrawn through the fluid in the syringe. These air bubbles cannot be withdrawn when the point of the needle is still in the structures of the chest wall. Thus by exerting traction on the piston of the syringe while the needle is traversing the chest wall air bubbles will come back into the syringe as soon as the needle point enters the pneumothorax cavity, and hence the exact position of the inner surface of the parietal pleura can be accurately determined. Again, by cultivating the sense of touch, one can tell by the feeling of resistance to the needle point that the outer surface of the parietal pleura has been reached. On pushing the needle through the membrane one can feel a definite diminution of resistance and even a slight elastic recoil. By these two methods, the one visual and the other tactile, the position of the pleura can be established. In practically every case the patient will be found to experience a definitely localised "neuralgic" pain while the needle is passing from the outer to the inner surface of the parietal pleura.

Medical Societies.

HARVEIAN SOCIETY OF LONDON.

A MEETING of this Society was held on Nov. 8th. The chair was taken by Dr. HERBERT FRENCH, and Dr. H. P. BAYON read a paper entitled

A COMPARISON OF SOME ASPECTS OF CANCER IN MAN AND LABORATORY ANIMALS.

He said that there were certain differences between animal and human cancer that should be taken into account before experimental results could be clinically applied. Neoplasms in laboratory animals could be grouped into three aetiological classes, of which the first only had no counterpart in clinical medicine. These classes were: (1) strain-tumours, inoculated, grafted or otherwise transferred from one animal to another; (2) tumours experimentally induced by tar, parasites, or other irritants; (3) spontaneous tumours. The first class differed from others in that they frequently retrogressed after incomplete operative removal. The second class were not necessarily as virulent or as easily grafted, but they infiltrated more actively and therefore could not be so easily cured by operation. Laboratory tumours were influenced in their inception and development by racial and individual properties which seemed to be localised in the surrounding tissue cells. Malignancy was the result of interaction between properties present in the multiplying and invading type of cell, and the reactions in the surrounding tissues, which remained passive or hypertrophied to a greater or lesser extent. There was morphological similarity between tumours of different animals, but microscopically identical neoplasms might differ considerably in transmissibility and rapidity of growth. The appearance of a cell in section only indicated its behaviour at a certain moment. As was well known, a tumour might be clinically malignant and pathologically innocent. Two distinct properties made up strain virulence: the rate of growth and the capacity for invasion. For example, the Jensen rat sarcoma grew rapidly, did not invade and often receded, while mouse tar-cancer grew slowly, invaded early and did not recede when once it was established. The host's resistance was difficult to measure, as repeated inoculations overcame it. All these properties seemed to be subject to recurring rhythmical variations.

Classification of Malignancy.

A grouping of degrees of malignancy was possible. (1) The worst degree, of which the small round-celled sarcoma was the type, was inoperable and rarely regressed. (2) The second grade demanded complete and early surgical removal, as it rarely regressed. (3) The third class was a slow growing tumour—e.g., endothelioma, perithelioma, and fibrous and endothelial neoplasms. These often regressed and partial removal was often followed by absorption of the remnant. Even a late case should be treated surgically. Animal experiment showed how much the result of operation depended on the skill of the operator. The rapid growth of a number of large cells put a strain on the organism, perhaps comparable with that of pregnancy, and even if the growth were completely removed the animal might not recover. Microscopy, although at times it might mislead, remained the best single method of diagnosis.

Prof. E. H. KETTLE pointed out what enormous strides cancer research had made in improving knowledge of the cancer process, even although it had not gone far towards finding cause or cure. The usefulness of the "strain cancer" had practically been exhausted, except as a field for the study of certain therapeutic agents. It was completely artificial and more nearly resembled a tissue culture than a primary natural cancer. Induced cancers, on the other hand, were in every way like spontaneous

human cancer. The laboratory worker could produce cancer in a high proportion of animals in a reasonable time with perfect regularity; he could modify the production, analyse the factors which led to it, and reproduce phenomena which actually occurred in human cancer. The total cancer incidence was about the same for every species of animal and for every race of man, but the organ incidence differed. Cancer of the breast and uterus reached high figures in this country, but was low in Holland, where the total was made up to a greater extent by cancer of the alimentary canal. The explanation of this curious difference probably lay in the factor of immunity. Apparently growth of one cancer inhibited the development of cancer elsewhere. The recognition that neoplasms occurred in all species of animals must make it clear that cancer was not to be ascribed to influences of diet or civilisation.

Mr. D. C. L. FITZWILLIAMS said he found it very hard to regard the single adenomatous cancer and the multiple epitheliomatous cancer as more nearly related than first cousins, and some animal cancers as more than second cousins to human growths. The Rous tumour was nearer a granuloma. It was a curious thing that if a far cancer could be produced in a mouse in a given number of days, a second cancer could be produced by painting a different area simultaneously in half that number of days—i.e., with only half the irritation required to produce the original growth. The inhibition which prevented all other precancerous cells from invading the basement membrane of a breast-duct when once one of their number had become definitely cancerous was a most strange thing. He had ceased to believe in the radical operation for mammary carcinoma; if the one small cancerous area could be reached and removed the patient was cured; if the lymph glands were invaded, the lymph was flowing in another direction and the cancer had already been conveyed to the internal organs, whence it could not be removed. The number of cancers that would shrivel up if three-quarters of their substance were removed was striking. Spontaneous cures did occur. Sometimes the patient's resistance would hold the cell in check for many years and then break down; the cancer cell must have been living all that time, for it would then grow with extraordinary rapidity. The gravest form of breast tumour was carcinomatous mastitis, usually sent in to hospital as a breast abscess; for these cases nothing could be done.

Neoplasms in Animals.

Prof. FREDERICK HOBDAY said that malignant tumours were very common in animals. Insufficient stress had been laid on the ubiquity of cancer, and collaboration between veterinarian and physician was of the utmost importance. Many questions called for answer. Why was cancer so uncommon in the animal uterus? Why was a malignant tumour of the normal testicle of the horse most rare while in the cryptorchid testicle it was very common? Why did veterinary surgeons constantly meet cancer in the penis, the vulva, the frontal sinus, the orbit, and the membrane of the eye? The smallest growth on the membrane of the eye in a cow or a horse was a most alarming thing to the veterinary surgeon. In the dog the commonest site was the tonsil, followed by mamma and testicle. Rodent ulcer was not uncommon in the cat. Infective growths of the penis and vulva of the dog had been a very grave trouble, especially among bulldogs, but had been practically stamped out by insisting on veterinary examination of every dog and bitch before service and by surgical treatment.

Prof. TOM HARR observed that the problem of cancer had passed far beyond the sphere of the clinician; the more one saw of the disease in animals, the more one felt that only the research worker could throw light on the problem. It was often extremely difficult to distinguish between a neoplasm and a granuloma, and glaring mistakes had been made through the failure of animal experimenters to benefit from the experience of veterinarians.

Prof. C. A. PARNETT did not think it possible to distinguish three grades of malignancy. The essential

thing was that certain cells were beginning to divide and to separate; the cement was gone. It was impossible to tell whether or not some of these cells had disseminated cancer through the body. There must be some underlying factor common to all the forms of irritation that produced cancer; what could be more irritating than shaving? Yet it never caused malignant growths.

What, interpolated Prof. HOBDAY, could be more gravely irritated than the udder of a cow? Yet cancer of that part was extremely rare.

Dr. F. COKE asked why arsenical cancer sometimes had such a long incubation period, and whether there was any incubation period between the removal of a growth and the time when immunity to further growths began.

Mr. FITZWILLIAMS referred to statistics which showed that American immigrants kept their racial cancer incidence for a certain period and then merged into the general American incidence-ratio. The professional incidence was also most curious.

Dr. BAYON, in reply, urged clinicians never to lose courage with any tumour; not everything that was cancer was malignant and not everything malignant was cancer. There was no 100 per cent. diagnosis or treatment, and coöperation between clinician and pathologist gave the best results. He regarded cancer as an absolutely localised condition, unlikely ever to be diagnosed by a general reaction.

MEDICAL SOCIETY OF LONDON.

AT a meeting of this Society held on Nov. 12th under the presidency of Dr. WALTER CARR, a discussion on the

MEDICO-LEGAL ASPECT OF FRACTURES

was opened by Prof. E. W. HEY GROVES, who delivered the address printed on p. 1017. He was followed by Dr. JAMES NEAL, who said that the position with regard to the treatment of fractures was from the legal point of view essentially the same as for all other forms of treatment and was governed by the implied contract to exercise reasonable skill and care. The jury had to decide whether or not reasonable skill and care had been exercised in any particular case, but had not to fix the standard. That had been fixed by the law as the amount of such skill and care as would have been exercised by the ordinary reasonable practitioner in the same branch of the profession. The term "reasonable" could only be applied relatively. A rural practitioner could not be expected to possess the resources of a hospital surgeon. The usual basis of a claim was failure to diagnose, although the treatment of a recognised fracture might be questioned. Resulting deformity, loss of function, or non-union might be the cause of action and the claim might then be difficult to rebut. Patients to-day expected far more perfect results than formerly, and the doctor might have to manipulate, fix, and radiograph several times until a perfect position was obtained. Each and every detail of the treatment might be challenged, even instructions to nurse, masseuse, or patient. Failure to exercise reasonable skill and care alone rendered a doctor liable to damages, and it was of the utmost importance to adopt routine precautions and to avoid any appearance of carelessness. Detailed and frequent examinations were of the greatest value in court. Very few claims made against doctors actually went to trial, and in most of these there had been some very definite omission, usually of a radiogram. X rays should be employed: (1) whenever the diagnosis was in doubt; (2) after fixation of the fragments; (3) a week later, to be sure the position was satisfactory; and (4) later still, to confirm the maintenance of the position. It was wise to have a second opinion on any difficult or unusual case. If reasonable care and skill were exercised from start to finish doctors need no more fear litigation after a fracture case than after any other. The real difficulty

was that the question of negligence was decided by a jury, and that once the jury had found negligence, on the flimsiest of evidence, there was little hope of a successful appeal. Dr. Neal could not subscribe to Prof. Hey Groves's three suggestions for minimising the peril of the doctor. The Medical Defence Union had always been advised that no form of indemnity would protect a doctor from an action for alleged negligence, and it might make him even less careful than he would otherwise have been. The suggestion of requiring doctors not to give evidence against their colleagues was utterly impracticable and would not solve the difficulty. Anything likely to lead the public to believe that the first consideration of the doctor was his own interests would make him suspect in everything he did. An expert assessor would be highly dangerous, for he might hold the most peculiar views on the matter in dispute, and if the judge was to be influenced by him the benefits of skilled cross-examination of medical experts would be nullified.

Mr. ZACHARY COPE said that even X rays often gave contradictory evidence in neglected fractures of the hip. Further, changes might take place in a few weeks which made the line of fracture difficult to see. X rays were very troublesome to interpret, and grave charges might be made on evidence which was capable of contradictory interpretations.

Surgeon-Commander A. GASKELL said that the Navy had very many fractures though not many legal actions. His conclusion was that the most dangerous person was the optimist who told the patient all was well, especially in fractures about the elbow-joint. The proper attitude of the medical man was to be pessimistic, and to prepare the relatives for the bad result which would occasionally follow even the best treatment. A second opinion was one of the chief safeguards against legal action. Some results looked deplorable in radiograms but were functionally excellent.

Mr. R. C. ELMSLIE said that in the Wood Hill case he had given an exact duplicate proof of his evidence to both sides and left it to the solicitors to decide which should call him. The evidence in that case on the instructions given to the patient had differed so widely that it was very difficult for a jury to assess what had actually happened. Moreover, the doctor had kept no record of the site of fracture. The moral was to keep most careful records of what was ordered and of what was found on examination. In another case a copy of a letter written three months before had been instrumental in preventing action against a practitioner.

Mr. DONALD ARMOUR said that doctors were apt to become advocates as well as witnesses; he did not agree that it was necessary to give evidence on one side or the other. In a similar case he had refused to furnish proof of his evidence and had declared in the witness-box that he appeared on subpoena and not for either side. The judge had upheld this attitude throughout.

Dr. E. M. CALLENDER quoted a case where a radiogram taken by a local chemist with ancient apparatus had caused a wrong diagnosis. The possession of very old apparatus might be a positive danger.

Mr. H. A. T. FAIRBANK also spoke of the danger of trying to form an opinion on imperfect radiograms. Trying to save the patient's pocket in this way let down both patient and practitioner. The surgeon, in doing his best for his patient, sometimes had to "give away" the doctor by recommending operation, but he must absolutely refuse to criticise former treatment, however hard it might be to refrain. He should say that, not having seen the case at that time, he could not assess the difficulties. If they said: do you think operation would have been advisable earlier? the surgeon must hedge. Before giving any opinion of the rights or wrongs of the case the surgeon ought always to see the former practitioner privately. It was unwise to tell the patient that he would not say anything before he had seen the doctor, because that involved him in giving an opinion afterwards, which was often better avoided. The

idea of a medical assessor was excellent; he would be able to help the judge in estimating small amounts of displacement and the like.

Mr. WARREN LOW said that X rays were an excellent servant but a hard master; doctors should never become slaves to the "X ray habit." X rays were much more useful after the fracture had been dealt with than before, and treatment should never be delayed for the radiologist. Every treatment was a process of trial and error, and patients could often be made to understand that the failure of the first treatment did not mean inefficiency or negligence. The indemnity method of protection was quite out of the question. The county court judge was not obliged to ask or to follow the opinion of the assessor at present, and the high court judge often would not do so if medical assessors were appointed. Nevertheless, only along those lines would doctors get any assistance from the bench.

Mr. ARMOUR related an experience with a medical assessor in the county court. The case was one of fractured femur and the assessor a very distinguished consulting physician.

Dr. REDMOND ROCHE related cases in which the taking of a radiogram had been disastrous. Two were obvious Colles's fractures not shown in radiograms taken by highly skilled radiologists. X rays were not absolutely essential to diagnosis and treatment. Clinical evidence, judiciously exercised, should be the deciding factor as to whether or not a radiogram should be taken. The profession ought not to allow the radiologist to persuade the bench and the public that a doctor who had not taken a radiogram had not fully performed his duty.

Mr. W. E. TANNER said that "simple fracture" was a most unfortunate term, and proposed instead the use of "open" and "closed."

Dr. ANTHONY FEILING said that the suggestion of discussion between "accuser and accused" was Utopian; after such a consultation in private the evidence of both would be looked on as suspect in court. He capped Mr. Armour's story with another county court case in which four neurologists gave evidence that the onset of paralysis agitans had no connexion with a previous slight scalp injury. The judge ruled otherwise, his assessor agreeing with him. The assessor was a surgeon.

Mr. H. W. CARSON quoted Lockwood's aphorism that what came out of a broken bone was not red marrow but black ingratitude. The public was wrongly educated, and thought that all fractures could be treated with a perfect functional result, which was in fact unattainable in the hands of the best orthopaedic surgeons. They were also misled in their opinion of the value, importance, and inevitability of an X ray photograph. Radiograms were very difficult to take and still more difficult to read. The public should learn that a single photograph in an unknown plane was most misleading and that reliance must not be placed upon it.

The PRESIDENT spoke of the dilemma of the physician between the command that every fracture be radiographed and the grave warning that the results of radiography might cause serious trouble.

Prof. HEY GROVES, in reply, explained that by "accuser" he meant a medical man who had impugned the results of a colleague in a way that he could not have done had he been aware of the facts of the case. The adoption of a second line of treatment did not necessarily condemn the first. Mr. Low had rightly said that X rays should be our servant and not our master, but we could not afford to neglect their service. They should be regarded as secondary to clinical examination.

Dr. NEAL, in reply, emphasised that he only regarded a radiogram as essential in cases of doubtful diagnosis. The last thing he wished to suggest was that a medical man should rely mainly on it for diagnosis. Its great value in court was that it was something objective, which the jury thought they could understand, and it went a great way towards deciding the case.

ROYAL SOCIETY OF MEDICINE.

SECTION OF PSYCHIATRY.

THE Presidential Address to this Section was delivered by Sir MAURICE CRAIG on Nov. 13th and was entitled

A Survey of Some Conditions Conducive to Mental Disturbance with Suggestions as to their Treatment.

He agreed wholeheartedly with the belief that much mental disorder is preventable; the fatalistic attitude of the public was pathetic but the apathy of the medical profession was harder to understand. The influence of stresses upon the mind was as important with the normal man as with the abnormal, and the mental reaction might be the determining factor in recovery from any condition. The study of the mind was a study of interaction and relationship. Granted that inherited tendencies largely determined the danger areas in any given mind, the physician should try to find what stresses might reinforce that tendency so as to make it operative. One of the most important potential factors in the production of mental disorder was variation in sensitivity. Hypersensitivity was frequently associated with weak inhibition or lessened control, and might be followed by physical or mental changes. On the mental side the changes would be in the emotions and would carry inevitable bodily changes with them. It was therefore most important to treat the hypersensitivity before the emotions became involved. Certain types of children could be kept continuously on small doses of bromide; grs. 2½ for a child under 4 and twice that amount for one over 4. Children who were almost uneducable from their over-reaction to stimuli might, under this treatment, become quiet and teachable. If the dose were withdrawn they would regress slowly, sometimes even developing epileptic fits. This suggested that small regular doses of bromide might be prophylactic against epilepsy. In the same way, grs. 5 of bromide a day might be most valuable for tropic-dwellers and for certain types of active men and women. Pavlov, in his work on the conditioned reflexes in dogs, had remarked:

"It must be noted that as a result of the administration of bromides there was no diminution in the magnitude of the positive reflexes; on the contrary, they were extremely constant. According to these and all previous experiments bromides should not be regarded as sedatives diminishing the excitability of the central nervous system; they simply regulate the activity of the nervous system by strengthening the intensity of internal inhibition."

The President's clinical experience supported this view. A small dose of bromide taken regularly over many years did not diminish the mental powers but in fact increased them, no doubt through preventing wastage. In larger doses bromide could be an extremely toxic drug, and its beneficial effects were lessened or destroyed. There was much to support the view that mental disorder was often due to the weakening of lowered inhibition and not to any positive condition. When the inhibitory function had become weak the emotions became involved, and this in turn caused preoccupation and false reasoning, and in time failure of adaptation to environment. All this was accompanied by corresponding physical changes, and after weeks or months it might be difficult to decide the initial cause of the mischief. Clinical experience favoured a sceptical attitude towards the endocrine system as primary cause; the changes in the vegetative nervous system were usually secondary, although when established they might have an important bearing on the illness. Accurate and careful case-taking was essential in seeking the first cause. Here as in everything else there were many sides to truth, and each physician tended to find his own specially dominant. Much might be done to localise an illness by pointing out to the patient the dangers of false reasoning about his symptoms, the direction in which his

reasoning would lead him, and the beginning from which false reasoning had arisen.

Insomnia.

The fact that healthy people could do without sleep at will, he said, did not mean that sleeplessness was harmless to everybody; it was for the physician to discern those who were likely to suffer seriously. There was much experimental and physiological evidence for the importance of sleep. Pavlov had distinguished two types of neurotic dog—in one the inhibitory function, and in the other the excitation of the cortical elements was affected. In the maniacal patient hypnotics were of little use and even seemed to increase the excitement, while the patients recovered spontaneously if left alone—like Pavlov's second type of dog. But in the other kind of patient sleeplessness was quickly corrected by suitable methods. Addiction was an extremely rare sequel to the prescription of ordinary sedative drugs, and the addict was usually a person from whom hypnotics had been withheld until he had reached a state of terror; it was to avoid a repetition of this terrifying experience that he clung to his drug. The term "addiction" most certainly ought not to be applied to a person who took a sedative every night on medical advice and thus preserved sleep, good health, and full mental activity. "Sleeping draught" was another term used incorrectly; properly it could only be applied to amylene hydrate and paraldehyde, which would produce sleep whenever they were given. The barbitone group, for instance, caused no desire for sleep if given in the daytime, and further research might show that their action was to strengthen a weakened inhibition, and that sleep was only a secondary result. Patients who showed evidence of exhaustion with defective sleep, due either to advancing years or to prolonged over-stimulation of the nervous system, might have their mental stability strengthened, so that their activity of mind remained on a high level for many years, by taking a small dose of dial or medinal every night. There was no evidence of any deleterious effect. Sedatives should be given over prolonged periods, and there was never any difficulty in withdrawing them when required. Daily medinal might moderate the phases of a manic-depressive mental disturbance.

The seriousness of insomnia in children was seldom fully appreciated. In some it would cause nutritional and digestive disturbances, in others emotional difficulties or mental confusion, and in course of time both physical and mental deterioration would appear. Grs. 5 of potassium bromide, with or without grs. 5 of chloral hydrate, every night for some time was excellent. Prolonged treatment was necessary to prevent relapses and induced a much higher level of physical health than short courses.

Minor mental disturbances were not uncommon after surgical operations and for their prevention sleeplessness must be relieved immediately. Some surgeons gave ½ drachm of paraldehyde per stone weight of the patient rectally on the operating table, or 1 drachm rectally an hour before the operation for very apprehensive patients, so that they never knew they were being anaesthetised. Medinal, dial, or allonal could be given with profit for some days before and some weeks after an operation, and would make convalescence more rapid and complete if the patient were at all nervous. If medical men prescribed effective sedatives for insomnia there would be less taking of drugs by patients on their own initiative. Patients did not tend to go on taking drugs after sleeplessness had been corrected.

Toxaemia.

Almost anything could act in a toxic manner, the President said, provided the nervous system were sensitive or had an "idiosyncrasy" towards it. The difficulty in diagnosis arose when the mental syndrome was not typical of toxæmia. The longer the condition of focal sepsis had lasted the more difficult and less effective treatment became. Medical

men should devote more time and study to mind reactions, for minor mental disturbances might be the earliest indication of physical disease due to some infection. Insomnia was frequently associated with toxæmia, often preceding it and allowing the toxic process to become active. Serious mental symptoms could often be prevented by treating the insomnia at once. Each person had his own way of reacting to stress, internal or external, mental or physical. Much false reasoning or rationalising resulted from the failure of the doctor to explain the mental condition or to appreciate the morbid sensibility of the patient. If the faulty attitude of a patient to stress was due to weakened inhibition it was unnecessary, and might be harmful, to spend months in tracking the original cause. Psychological medicine would gain from making the language it used more simple. Clinical experience had, year by year, driven the speaker back into general medicine. To him the theory of weakened inhibition explained so much: why certain brilliant children or adults broke down and why at first there was no interference with their normal mental activity, which only became involved as sleep and other bodily functions became affected; why a toxæmia might affect the nervous system of certain people; why a breakdown might follow surgical operation; why some people broke down from over-stimulation or with advancing years; why some persons relapsed when certain treatment was discontinued; why treatment should at times be continuous and why patients might remain in good health and full mental activity for many years under treatment. Research from that standpoint would bring about much knowledge of value in prevention and treatment of "functional nervous disorder."

COMBINED SECTIONS OF THERAPEUTICS AND TROPICAL DISEASES.

THE SPECIAL USES OF ANTIMONY.

A JOINT meeting of these Sections was held on Nov. 13th to discuss the special uses of antimony. Prof. J. A. GUNN, President of the Section of Therapeutics, who took the chair, said that Valentine, who was largely responsible for the introduction of antimony in modern medicine, stated that one man's life was too short to become perfectly acquainted with all its mysteries. It had become clear, said the chairman, that even the 300 years which had elapsed since then had not sufficed for the discovery of all the mysteries of antimony.

Dr. J. B. CHRISTOPHERSON, in opening the discussion, first dealt with the question of the early use of antimony. In England it was of but little account as a medicinal agent until the sixteenth century, but it had figured in an interesting way in the evolution of medicine since remote times. First it was used as a cosmetic, and later as a medicinal application for the eye. From 1500 to 1825 in this country people used antimony empirically for many diseases; and from 1905 to the present day could be looked upon as the period of its scientific administration. It belonged to the same chemical group as nitrogen, phosphorus, bismuth, and arsenic. The close chemical relationship between antimony and arsenic led to the idea that their biochemical reactions were similar. The Assyrians found the metal near Ispahan in Persia, and were the first to use it as an article of female adornment. It was still used by Arab women, by whom it was called the eye-paint. Doubtless the Assyrians taught the Israelites how to use eye-paint. Certainly it was used a long time ago for the treatment of granular eyelids, also as an astringent for eye discharges, for ulcers, burns, recent wounds, and dog-bites. In the sixteenth century Paracelsus introduced antimony into medicine, and he strongly recommended its use for the plague, under the term "mercurius vitæ," though it contained no mercury. It was in 1604 that antimony found a place in the British Pharmacopæia. In 1619 "the Earl of Warwick's powder," containing antimony sulphide,

appeared in Italy, and this was the precursor of tartar emetic, the most important of the antimony derivatives. Louis XIV., when 19 years of age, was seized by an illness which baffled the physicians, but a quack was said to have cured him by giving him tartar emetic. Following a violent controversy concerning the drug in 1566, it was banished from medicine for a hundred years. In 1822 Prowse obtained the sesqui-oxide of antimony, and there were two famous antimony preparations, James's powder and Plummer's pill. Pulv. antimonialis was the official substitute in 1787, and it was still in the 1914 British Pharmacopæia.

In 1906 two workers in the Pasteur Institute, Paris, proposed the use of antimony salts for trypanosomiasis. In the same year Plimmer and Thompson, at the Lister Institute, tried, on the suggestion of Cushing, antimony potassium tartrate. Of all the various drugs used for trypanosomiasis, sodium antimony tartrate had the most marked influence on the disease in the human body. Its first use was by subcutaneous injection, but sloughing and the formation of abscesses followed. And oral administration did not prove more satisfactory. In 1906 a very important discovery was made—namely, that antimony tartrate could safely be injected intravenously, and cases of cutaneous leishmaniasis were cured by potassium antimony tartrate. In 1915 cases of kala-azar were cured with it in Sicily, and this was repeated by Sir Leonard Rogers in India and Dr. Aldo Castellani in Ceylon. The speaker himself, in 1917, had investigated the action of potassium antimony tartrate in bilharzia. In 1913 two workers in Brazil had successfully treated granuloma inguinale with potassium antimony tartrate intravenously, proving the important fact that it was efficacious not only in two protozoal diseases, but was also a specific in a bacterial infection. Later it was shown to be specific for a helminthic affection too. It was probably specific for rhinoscleroma, which was caused by a diplococcus of the Friedländer type.

THE PRESIDENT said his personal experience with antimony compounds was only slight. The use of antimony for specific diseases was largely a matter of the last 20 years. In early times it seemed to have been used for every known disease, and this greatly reduced the credit attached to the observation of which ailments it seemed to benefit most. In its earlier use it was mixed with such a variety of compounds and was prepared in so many ways that one wondered whether some such form as that employed to-day was not happened upon. Research on antimony had gone on *pari passu* with research on arsenic. In the case of arsenic the pentavalent compounds had first been tried, then gradually the workers had passed on to the trivalent ones, such as salvarsan. The reverse order was followed in regard to antimony. It had been shown that if a compound did not act on trypanosomiasis it probably would not act on bilharzia. Trial with other substances in place of tartaric acid—such as citric or lactic—did not give better results. Lithium had now largely replaced the potassium salt. The substitution of ethyl had given good results in trypanosomiasis. The first pentavalent compound which was made was an analogue of atoxyl. It was tried in trypanosomiasis, but it was no better than potassium antimony tartrate. The next preparation made was stibetyl; this was tried in leishmaniasis and in experimental trypanosomiasis. It was effective, but the results were not dramatic. Next, one of the hydrogen molecules was replaced by chlorine, and the substance was named stibosan, the von Heyden "471." It was a distinct success. Urea compounds had also been made. One was stibol. A substance used a good deal now was stibamine glucoside, and there was no doubt about its efficacy in kala-azar. For the latter disease the best drug was considered to be "693." Attempts had also been made to combine antimony with dyes; it was said that only the compounds which stained trypanosomes were active. There had not yet been any report made about their

action on man. He asked whether any member had used antimony *per rectum*.

Dr. GEORGE LOW first spoke of the successful experiments of Plimmer on rabbits infected with trypanosomiasis. But when antimony was injected subcutaneously in man the local reaction was so severe that it had to be discontinued. It was then given orally, but the vomiting which followed administration of a large dose ruled that method out. On the Congo, where many were dying of sleeping sickness, it was tried intravenously, in small doses at first. The expected sloughing of veins did not follow, and by gradual increments massive doses could safely be given. Even grs. 2½ to 3 could be given without causing more than a cough. It was next tried in leishmaniasis, and Castellani used it with success for kala-azar in Ceylon. Then came the great discovery by Christopherson of the efficacy of the metal in bilharziasis. When the speaker began to study tropical medicine, bilharzia showed a high mortality, but Christopherson's discovery brought the figure down greatly. Large doses, however, must be given. For ulcerating granuloma a total of grs. 54½ would bring about a complete cure in one case, while in another this did not ensue after grs. 114. Of the various derivatives he had used, the one he liked best was stibamine glucoside. Neostam could be used intramuscularly for children without harm.

Dr. PHILIP MANSON-BAHR said that the new pentavalent compounds had no effect on *Schistosoma hamatobium*. The more poisonous the compound used, the more effective it was against schistosomiasis. Antimony killed off the bilharzia worms by a slow and painful process; it was specific for the ovarian tract of the female worm, and neutralised its egg-laying capacity first, and then the worm slowly died. Good results were not claimed for the pentavalent compounds in schistosomiasis. The new pentavalent compounds, if exposed to great heat before being injected, were rendered practically useless. An important point was told to him by Dr. H. M. Hanschell—namely, that if antimony was dissolved in a 5 per cent. glucose solution, many of the poisonous effects were thereby obviated. Many patients complained so much of rheumatic pains after injection that further injections were rendered almost impossible, but since he adopted Dr. Hanschell's advice, he had not heard such complaints. It was a distinct advance in technique. Some kala-azar patients seemed to be antimony-resistant—i.e., no dosage cleared up the illness. In such cases Dr. Manson-Bahr advocated a trial of them all in turn until the particular efficacious one was found. Even six-tenths of a gramme (nearly grs. 8) should be given. The reaction was grave, but afterwards the clinical improvement was obvious. A curious fact, of which he had not seen any explanation, was that Leishman-Donovan bodies could be recovered and grown in culture almost up to the time of the patient becoming quite well of his disease. He had had a case of ulcerating granuloma, lasting three years, in which grs. 300 of antimony tartate was given, the final result being good. In this disease the pentavalent compounds of antimony were more valuable than the original tartar emetic.

Dr. ALDO CASTELLANI said he believed he was the first to use antimony in the treatment of Indian kala-azar. Previously he had used tartar emetic in other diseases, for instance, in yaws. He had also employed it in broncho-spirochaetosis, the existence of which some denied, and found it very useful. He mentioned that he had been carrying out investigations into the closely allied element phosphorus. The great difficulty concerned its method of administration. The oral route was very unsatisfactory, but it could be used conveniently by the subcutaneous method if the phosphorus oil of the British Pharmacopoeia were employed—i.e., 2, 3, 5, up to 10 M of the phosphorated oil. It produced no pain. In chronic malaria it was an adjuvant to quinine, and he advised it in ticks and oedemata, with good results.

He had also used it in dermal leishmaniasis, and in most of the cases phosphorus answered better than antimony. If there was no ulceration 5 M was the quantity injected twice a week. When the nodule was ulcerated, the technique was very simple; the ulcer was cleaned up and a few drops were let fall on the fundus of the ulcer from a glass rod.

Dr. H. B. DAY said he had seen many thousands of cases of bilharzia treated by Dr. Christopherson, and he knew of no instance in medicine in which one could so intimately and accurately follow the therapeutic result. The progress could be watched day by day under the microscope. He described the progress of a serious case from the time it was first seen to its ultimate cure, remarking on the importance of concentrating treatment in the first week.

The opener briefly replied.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

At a meeting of this Society on Nov. 1st, with Mr. GEOFFREY BATE, the President, in the chair, Mr. St. G. B. DELISLE GRAY read a paper on the

Injection Treatment of Varicose Veins.

He began by outlining the anatomy of the superficial veins of the lower limb as described by Kosinski,¹ and said that the anatomical factors making for varices were: (1) The height of the column of blood. The average length of the great saphenous vein being 85 cm.; (2) the thinness of its walls and lack of muscular support; and (3) possible variations in the anatomical course of the small saphenous and its anastomotic channels. The first intravenous injections of drugs had been made on animals in 1657, at the suggestion of Sir Christopher Wren, the architect of St. Paul's Cathedral, but intravenous therapy had been impracticable until the invention of the Pravaz syringe in 1851. Shortly after this date experiments had been made with the injection of solutions of ferric chloride into varicose veins; there had been many successes, but also many failures due to septic sequelae, embolism, and the like. During subsequent years various solutions had been used for injection, and there had been many successful cases, although some caused great pain to the patients, whilst others caused sloughing, scarring, and recurrence. He himself had found that sodium salicylate caused severe pain, though admittedly the results were excellent. He now used quinine and urethane, and always gave the injections with the patients standing up. He saw no reason for injecting the fluid slowly, as it must surely militate against the success of the injection if the fluid became diluted. In women it was important to exclude pregnancy as a cause or a concomitant of varicose veins, as the injection of quinine might possibly lead to abortion. After giving an account of a series of experiments at the Mayo Clinic by L. G. Rowntree and Takuji Shionoya,² with the object of directly observing thrombus formation, he drew attention to the fact that most solutions used in the injection treatment of varicose veins were self-sterilising. In the treatment of hemorrhoids he used 20 per cent. carbolic acid, and he suggested that similar fluids might be injected into subcutaneous naevi, and that varicocele might be amenable to treatment by injection. The alleged risk of quinine blindness after injection of quinine he regarded as negligible.

After reading the paper, Mr. Gray showed a table designed by himself for the patient to stand on, and demonstrated two cases.

Dr. H. M. GALT showed microscopical slides illustrative of changes in the vessels.

Reviews and Notices of Books.

THE PRACTICE OF REFRACTION.

By W. S. DUKE-ELDER, D.Sc. St. And., F.R.C.S., Assistant Ophthalmic Surgeon, St. George's Hospital; Assistant Surgeon, Royal London Ophthalmic (Moorfields) Hospital. London: J. and A. Churchill. 1928. With 208 illustrations. Pp. 410. 12s. 6d.

Mr. Duke-Elder says in his preface, and we agree with him, that most of the principles of optics, so far as the clinical practice of refraction is concerned, can be understood and appreciated in non-mathematical terms. With this end in view, he has succeeded in producing a thoroughly practical book which should be of great use to students, who are referred for a more complete presentation of the theory to the current works of Charles Goulden and A. S. Percival. There are still some questions connected with the practice of refraction as to which authorities are not unanimous. One of these is as to whether or not the ciliary muscle can act unequally in altering the curvature of the lens in different meridians, or whether it always acts on all meridians equally. The matter is not one of merely theoretical interest, for on it depends the rationale for the correction of small errors of astigmatism. It is now generally held that in certain patients suffering from headaches this correction is a matter of great importance. Ernest Clarke attributes such symptoms to the strain to which the ciliary muscle is put in contracting unequally in order to correct these small errors. Duke-Elder denies this. Yet he says that the form of the lens when relaxed under atropine is completely different from that found in the accommodated or partially accommodated state. If this is not due to unequal ciliary contraction how, then, is it caused? The answer, according to Duke-Elder, is by an alteration in the shape of the anterior surface of the lens when the tension of the capsule is relaxed, this surface becoming not only more convex but paraboloid, and a lenticulus being produced. In this way, he says, a minute amount of astigmatism which may be found under cycloplegia and mydriasis will no longer exist when the effect of the atropine has worn off, and since the object of glasses is to correct the errors of refraction present when the eye is in its normal condition, the correction of these small errors which are only found under atropine is contra-indicated. It will be seen that the difference of view of Duke-Elder on the one hand and Ernest Clarke on the other is fundamental. There is no question but that in cases where there are no symptoms, and where the correction of a small error of astigmatism does not improve the natural vision, such correction is unnecessary and unwise, but, on the other hand, where there are distressing symptoms, such as headache, in nervous or highly strung patients, the experience of most modern ophthalmic surgeons is that it is amply worth while for the patient to wear glasses correcting his slight error, even though the improvement in vision may be negligible. If this is true, what can the explanation be except strain caused by unequal contraction of the ciliary muscle?

As to the methods of testing for glasses, Duke-Elder rightly lays the principal stress on retinoscopy, an art which, as he says, requires much painstaking practice, and cannot be learnt in a day. To determine the correct axis of astigmatism the advice is given to study the shadow when the appropriate sphere and cylinder are both in the trial frame. For exact work the position of the source of light, the choice between concave and plane mirror, the size of the hole in the mirror, and whether the hole is pierced or merely left unsilvered, are all matters of moment. Authorities are by no means agreed as to these details, and the learner should carefully compare their teachings and test them by his own practice. In cases of oblique astigmatism much can be learnt

by observing the changes in the obliquity of the shadow when one meridian is slightly under- or over-corrected. We do not exactly understand the author's meaning when he suggests that in certain cases the two meridians are not at right angles to each other. As to subjective tests, the recently introduced "duochrome" is explained, a test which depends upon the fact that the short blue waves of the spectrum are refracted more acutely and brought to a focus sooner than the long red waves. Readers are enjoined to make careful tests in cases of presbyopia and not trust to mere routine in this matter. Heterophoria is adequately but not exhaustively dealt with, and the explanation of the amblyopia of convergent squint leaves something to be desired. There is a useful chapter on the making and fitting of spectacles in which the rather difficult subject of *decentering* is dealt with, as also *distortions* due to tilting, tinted and protective glasses, and so forth. The appendices include useful tables reproduced from Percival's latest edition, and an up-to-date list of official visual requirements.

PRACTICAL SURGERY OF THE ABDOMEN.

By GEORGE H. JULLY, M.D., Chief Surgeon to the French Hospital, San Francisco. In 2 volumes. With 1291 illustrations. Philadelphia: F. A. Davis Company. 1928. Pp. 1275. \$16.

This is a manual for the practical clinician and presents a picture of what the surgeon sees in his everyday work. There is no systematic account of pathology, but the significant features of diseases are considered, together with important points which lead to a true diagnosis and anatomical facts which have a bearing upon surgical treatment. The author lays great emphasis upon the necessity for arriving at a correct diagnosis when possible, and stresses the importance of regarding the body as a whole in relation to its local diseases. His style is easy and attractive, in places almost conversational. The methods described are those he himself employs and relies upon; where he gives an account of a procedure of which he has no personal experience he makes a special note to that effect, and this candour inspires confidence. There are many interesting things and good pieces of advice in the book—for example, the recommendation to examine carefully the excised gall-bladder, to ensure that no damage has been done to the common duct before closing the abdomen, and the need for caution when at an operation for gall-stones the gall-bladder appears normal to inspection. The suggestion that gastro-jejunal ulcer is the result of too large a stoma is worth consideration, and a number of other useful points will be discovered by the reader. Some of the advice offered will not be universally acceptable, such as the use of the stomach-tube before gastric and gall-bladder operations, the advocacy of the Beran gall-bladder incision, and Y-gastro-enterostomy. The author makes out a very good case for the combination of urinary and abdominal surgery, believing that specialisation has gone too far for the good of the patient, and he includes in his second volume an account of urinary surgery and of abdominal gynecology. The illustrations are numerous. The majority of them are poor works of art, but they have the merit of explaining quite clearly the author's meaning.

POST MORTEM AND MORBID ANATOMY.

Second edition. By THEODORE SHENNAN, M.D., F.R.C.S. Edin., Professor of Pathology in the University of Aberdeen. London: Faber and Gwyer, Ltd. Pp. 664. 25s.

This book has been recast with a view to making it a text-book of special pathology as well as a manual for use in the post-mortem room. The arrangement of the subject matter corresponds, for the most part, to the order in which a post-mortem examination is conducted. It remains pre-eminently a book in which the author describes what he himself has seen. For

example, the section on bone-marrow gives the real facts as to the replacement of red marrow by yellow and discusses the chloromatous infiltration of the marrow sometimes seen in acute leukemia. Many subjects—for example, gastric ulcer—are admirably dealt with in a relatively small space. Brief pointed descriptions are given of argyria, industrial benzene poisoning, and poisoning by arseniuretted hydrogen and tetrachlorethane; these are missing in most post-mortem manuals of this size. The classification of nephritis is not good and the whole section dealing with this subject should be rewritten. It is almost incredible that we should be asked to believe that nephritis occurs in forms so varied as acute parenchymatous, acute interstitial, subacute parenchymatous, subacute interstitial, chronic parenchymatous, and chronic interstitial.

Apart from this our criticisms are merely of details. The statement that Addison's disease "depends upon inadequacy or diminution of the chromaffin cells" implies that the suprarenal medulla is essential to life, whereas all the modern evidence goes to show that this honour belongs to the cortex alone. No mention is made of carcinoma of the suprarenal cortex associated with sexual precocity. We challenge the statement that "in young individuals the coronary arteries may show syphilitic (proliferative) endarteritis." When syphilis affects the coronary blood-supply it does so by blocking the coronary orifices as a result of syphilitic aortitis. The section on carcinoma of the lung is good, but syphilis of the lung is given undue prominence considering its rarity. In the discussion on familial hemolytic icterus the statement is made that "there are no apparent structural alterations in the bile-ducts," but the important fact that gall-stones are found in 60 per cent. of cases is not mentioned.

The book is well printed on good paper, and profusely illustrated.

LYON'S MEDICAL JURISPRUDENCE FOR INDIA.

Eighth edition. By L. A. WADDELL, C.B., C.I.E., F.L.S., M.B. Calcutta and Simla: Thacker, Spink and Co. London: W. Thacker and Co., 2, Creed-lane. 1928. Pp. 812. Rs.20 = £1 13s. 4d.

THIS book has passed through eight editions in forty years and holds a high position in medico-legal circles. It is written principally for India, but it deals also with the various legal enactments and conditions in this country. In this edition the author has had the assistance of Lieut.-Colonel T. F. Owens (Rangoon), who has revised a great part of the work, and also of Lieut.-Colonel R. B. Lloyd, who is responsible for the chapter on blood stains. The student will find the book a most useful guide to the practice of forensic medicine in India. A considerable amount of new matter has been added, and the chapters on wounding and on the examination of blood stains have been greatly improved. In these chapters, however, a few points needing revision have escaped attention. The statistics are almost uniformly long out of date, and some of the various enactments of medico-legal interest of the past few years have not been noted; for example, the Infanticide Act (1922), the Administration of Estates Act (1925), or the Law of Property Act (1925), although the latter two statutes have completely altered the questions of survivorship and tenancy by courtesy which are discussed at some length in the book. The description of the poisons of special moment to practitioners in the East remains one of the most interesting parts of the work. In the general toxicology section, while certain parts have been well revised, others have been unaccountably neglected; the article on Cannabis Indica, which has a certain importance in India, is left as it was written by Lyon himself in 1889. Beaub's test, which is in regular daily use, is not mentioned, and the statement is made that there is no chemical test for the substance. A further example of lack of revision is seen where veronal is described as "a dangerous new drug," although

it is 25 years since it was synthesised by Merck. The section on the organic compounds of arsenic would bear expansion. The organic compounds of antimony are not mentioned at all, and although tartar emetic must have been employed in India for a considerable time for the treatment of bilharzia, it is not referred to in this connexion. The article on the Stas Otto process is excellent. A new feature is the insertion of photographic illustrations, for the most part very good, of various types of injury, which add greatly to the value of the work. The omissions to which we have drawn attention do not to any considerable degree detract from the usefulness of the volume, which must be considered the foremost work on Indian medical jurisprudence.

ELEMENTARY PATHOLOGICAL HISTOLOGY.

By W. G. BARNARD, Pathologist to University College Hospital, London; Formerly Junior Assistant Director of the Institute of Pathology at the London Hospital. London: H. K. Lewis and Co., Ltd. 1928. Pp. 70. 7s. 6d.

THIS book is practically an atlas. It consists of 176 illustrations, and contains only as much letterpress as serves to explain the figures. Technique is not dealt with at all. Although in a work of this size complete and detailed treatment of the subject is out of the question, the author has covered a surprising amount of ground. A description of the general phenomena of inflammation and repair is followed by sections dealing with the more characteristic infectious lesions. Certain degenerative processes and vascular lesions come next, and lastly the tumours. The descriptive matter is lucid and dogmatic, as it should be in a book of this type, and the illustrations are really admirable. The majority of them are photomicrographs, and it is obvious that great pains have been taken in the selection of preparations and the choice of "fields." Nearly all of them are clear and sharp, and though one or two fall a little below the general high level, they really do fulfil the purpose for which they are intended.

Dr. Barnard is to be congratulated on a book which will certainly be deservedly popular with students. It is beautifully produced and inexpensive.

CLASSIFICATION OF HEART DISEASE.

Criteria for the Classification and Diagnosis of Heart Disease. By a Committee: JOSEPH H. BAINTON, M.D., ROBERT L. LEVY, M.D., W. C. MUNDY, M.D., M.C., U.S.A., HAROLD E. B. PARDEE, M.D., Appointed by the Heart Committee of the New York Tuberculosis and Health Association. New York: Paul B. Hoeber. 1928. Pp. 91. \$1.50.

THE American Heart Association is performing a useful function in collecting information about heart disease from all parts of the United States. In work of this kind it is essential that different people should apply the same name to the same condition. To provide such a uniformity of nomenclature and to define the terms used is the object of the present volume which has been written by a committee of four, appointed by the Cardiac Section of the New York Tuberculosis and Health Association. The task can have been no easy one, and the committee deserves praise for its achievement. The book follows the general scheme adopted by the American Heart Association in dividing the subject of diagnosis into four main categories—*anatomical, physiological, aetiological* and what, for want of a better term one, might call "*economic*." To define the limits of normal variation has doubtless been one of the most difficult problems which the authors had to face, and in this matter they are bound to meet with a considerable amount of criticism. For example, on p. 80 it is stated that hypertension may be diagnosed when the systolic pressure is above 140 or the diastolic above 90. These figures are too low; 160 and 100 are the lowest values which would be accepted by most

cardiologists. Again, in speaking of cardiac enlargement (p. 37), the statement that "The left border of the normal heart does not usually lie more than 1 cm. to the left of the mid-clavicular line" is surely an error in the opposite direction. In adults the mid-clavicular line is a liberal estimate, and 1 cm. beyond it would generally be accepted as undoubted evidence of cardiac enlargement or displacement. These, however, are merely isolated points, and taking the book as a whole there is very little matter for criticism.

PIONEERS OF SCIENCE.

Seven Pictures of Struggle and Victory. By AMELIA DEFRIES. London: George Routledge and Sons, Ltd. 1928. Pp. 189. 5s.

THE contents of this book are divided into two parts, the first dealing with the living, "by whose wisdom we progress," and the second with the dead, "by whose light we live." The first forms the major part of the book: it consists of sympathetic studies of the life and work of four men of genius. These are Sir Jagadis Bose, F.R.S., the Indian botanist; Patrick Geddes, the biologist; Victor Branford, the sociologist; and Nicholas Roerich, the Russian painter. The second part is devoted to short sketches of the lives and discoveries of Sir Francis Bacon, Sir Humphry Davy, and Faraday. The choice of heroes is somewhat arbitrary. No doubt the world owes much to Sir Francis Bacon, but in pure science, considering the age in which he lived, Roger Bacon has perhaps an even greater claim to attention. The author is evidently imbued with the statement of Bose, that "the excessive specialisation of modern science in the West has led to the danger of losing sight of the fundamental fact that there can be but one truth, one science, which includes all branches of knowledge." The Indian belief, current for more than 4000 years, that whenever the country is in need the redeeming spirit will be reborn; "whenever the dharma decays and adharma prevails, then I manifest myself. . . . I am born again and again" is the main theme of the first part of the book.

MANUAL OF ZOOLOGY.

Sixth edition. By L. A. BORRADAILE, Sc.D., Fellow and Tutor of Selwyn College, Cambridge, and Lecturer in Zoology in the University. London: Humphrey Milford, Oxford University Press. 1928. Pp. 683. 16s.

IN this edition considerable alterations and additions are made in the chapters on sex, embryology, and evolution, and a concise account of helix is inserted. Minor additions, corrections, and alterations relate to amoeba, anodon, archæopteryx, paramecium, the nervous system of raja, and so forth. There are some 25 new illustrations.

From the foreword we learn that the author intends the book for the instruction of students working (a) for a preliminary medical or some similar examination, and (b) taking a wider course or a general course in zoology. For the latter class of student the book is excellent. For the medical or veterinary student the book is good in so far as it is dealing with the protozoa in general, the annelida, arthropoda, and vertebrata, but those sections intended as a link between zoology and the later medical studies might with advantage have been enlarged. Such sections are of vital importance not only in the curriculum of the medical student, but in that of the veterinarian. They are not sufficiently accurate in detail for students. For example, on p. 223, in speaking of the liver fluke, we are told "the cercaria, making its way up the bile-duct, grows into an adult fluke." The liver fluke is spoken of as the *Distomum hepaticum*, whereas the student in his later years will have to speak of it as the *Fasciola hepatica*. The same remark applies to trichocephalus and its now accepted name of trichuris, *Ancylostomum duodenale* for *Ancylostoma duodenale*, and so forth. On p. 151 we are told that in fission

in the trypanosomes "the flagellum . . . is doubled, in division," but this is not in accord with modern knowledge. The same may be said of the statement on p. 151 that "latent bodies" in the trypanosomes "probably can increase by binary fission."

If these sections were carefully revised and supplemented the book would become a most useful textbook for medical students. Without adding more than a few pages it could also be made completely adequate for the needs of veterinary students, for the medical and veterinary courses have much the same requirements in this respect. We are told on p. 147 that *Entamoeba histolytica* "inhabits the human intestine," but it is as important for the medical man as the veterinarian to know that this parasite is also found in dogs. On p. 224 the schistosoma is referred to as a parasite "which lives in the veins of man"; this might read "which lives in the portal veins of man and animals." Mosquitoes, lice, and house flies are dealt with, but the important tsetse-flies and bot flies are neglected.

In spite of these omissions the book will be found extremely useful, and the illustrations are excellent.

New Inventions.

AN ADJUSTABLE SPRING-LOADED EXPIRATORY VALVE.

THERE are many occasions in surgery when the anæsthetic of choice is nitrous oxide and oxygen given under pressure. For example, one or both pleural cavities may be opened without the occurrence of dyspnoea if differential pressure is employed. Several somewhat complicated American machines enable the anæsthetist to use positive pressure

with or without rebreathing, but with the simple sight-feed type of apparatus such as the "Boyle," it is only possible to obtain pressure with complete rebreathing. The object of the valve here illustrated is to enable a continuous pressure to be used with any desired amount of rebreathing or with none at all. The valve will be seen to resemble the standard 3-way attachment except that the simple expiratory flap-valve is replaced by a spring-loaded

blow-off, the tension of the spring being regulated by the knurled nut A which, in turn, is fixed by the lock-nut B. The pressure at which the expiratory valve opens can be seen by the manometer on the gas-oxygen machine, and can be varied from practically nil to 15 mm. Hg. It is rarely necessary to exceed 10 mm. Hg, and this pressure can be maintained without unduly distending the bag if this is made of rubber sheet, gauge 8 (instead of the usual gauge 10 for a 2-gallon bag). The internal construction of the 3-way mechanism has also been modified so that there is no restriction in the size of the gas-way in positions of partial rebreathing.

The valve was made at my suggestion by Messrs. Coxeter and Son, Ltd., 171-5, Pancras-road, London, N.W., and has proved quite satisfactory in practice.

C. LANGTON HEWER, M.B. B.S. Lond.

THE BACTERIOPHAGE IN ACTION.

THE question whether bacteriophage is effective within the body is of much importance to practical medicine. For if so specific and innocuous an agent were to prove capable of destroying bacteria in organs and tissues as easily as under certain circumstances it destroys them in the test-tube, it would fulfil a hope that has inspired bacteriologists since ever the germ theory of disease was put forward. From the early days of its discovery F. D'HERELLE has insisted on this aspect of bacteriophagic activity and has persistently claimed for it a supreme significance in the combating of disease. It has, he thinks, a dual rôle: first, as a therapeutic agent in individual cases where it develops in the body during the illness and constitutes the natural means of cure; secondly, as playing a larger part in the control and termination of epidemics. He visualises a naturally evolving epidemic as having two phases—one in which the causal organism is spread from person to person, and a second phase in which the bacteriophage makes its appearance, being liberated in the excreta of those who have overcome the infection. Water, flies, and other agents rapidly distribute it from host to host until the whole population has been contaminated, when the bacteria become impotent and the infection subsides. The epidemic is the spread of the bacteria; its decline betokens the spread of the bacteriophage.

Whilst these views are plausible and attractive, they have not been generally accepted. D'HERELLE claims dramatic results in various epizootics in which he has used bacteriophage as a mass remedy, but the careful work of W. W. C. TOPLEY and his collaborators in experimental epidemics of mouse typhoid has not supported the gospel he proclaims. Of more immediate interest, perhaps, to the practising physician are the results obtained in individual cases of disease. It is local infections such as dysentery, enteritis, pyelitis, and limited septic processes which lend themselves especially to treatment by the bacteriophage, and a number of scattered reports concerning them have come to hand from time to time. A large and controlled series, however, in which the agent has been extensively tried under unexceptionable conditions has been as yet wanting, and we therefore welcome two recent papers which give further information upon the subject. One of these¹ is especially valuable, as it summarises work carried out in India by D'HERELLE in collaboration with English medical officers, and under the aegis of the Indian Research Fund Association. The disease studied was cholera, and certain preliminary observations were made in Calcutta and the Punjab upon 33 patients. Twelve of these showed either complete absence of the bacteriophage from their stools at the time of admission to hospital or else the presence of a bacteriophage of slight or diminishing activity; all of them died. Five, on the other hand, had a very active bacteriophage in their stools, and they all rapidly recovered. In the remaining 16 cases a bacteriophage of feeble activity was found at the time of admission, and after showing some variation it finally became extremely potent. All these patients, also, ultimately recovered. On the strength of these and similar observations, which D'HERELLE has made in other conditions, the thesis is maintained that the presence of an active bacteriophage is essential to recovery. In the experiments designed to test this belief the bacteriophage was prepared, and the stools were examined for its

presence by Dr. D'HERELLE himself, whilst Major R. H. MALONE, I.M.S., was responsible for the treatment of the patients, and Dr. N. LAHIRI for the routine bacteriological examinations. The bacteriophage was administered by the mouth, diluted in water, every two or three hours. No other special method of treatment was employed, and the patients, all of whom had rice-water stools, remained in their own homes. Among 240 control cases there were 143 deaths—a mortality of 60 per cent.—which is said to be the average in the Punjab. Among the 70 treated cases, on the other hand, there were only six deaths, a mortality of 8.5 per cent. The controls were not selected in quite the same way as the treated cases, since they included persons who refused the specific treatment and those who came under observation on days when bacteriophage was not being given; but it does not seem likely that this would introduce any factors causing a wide difference in the series. The paper describing these results also gives information bearing on the effect of disseminating the bacteriophage amongst an infected community. Its introduction into water-supplies is beset with difficulties in India, since caste and religious beliefs stand in the way. Artificial dissemination was therefore seldom carried out, but D'HERELLE and his school believe that natural dissemination will readily occur in native villages as it does in animal epidemics. Cases are cited in which cholera ceased in a village within two or three days of patients being given the specific treatment, and four instances are given in which outbreaks promptly ceased after the bacteriophage had been introduced into the wells which furnished drinking-water. The claims made are thus extremely large, and as they have now been urged, in one form or another, for several years, it is very desirable that their merits should be strictly ascertained. We know well that a number of other experimenters have got no results approaching those reported by D'HERELLE, and often they have frankly failed. The cause of this, however, is said to be the use of strains of bacteriophage of insufficient activity; and the reply seems reasonable. There is urgent need of a full investigation under conditions acceptable both to D'HERELLE and to unbiased critics. If the bacteriophage really has this therapeutic and prophylactic value in cholera, there should be no difficulty in demonstrating it on a large scale in countries where the disease is present.

The use of bacteriophage in certain other infections has recently been reported upon by H. GRENET and ISAAC GEORGES.² They tried it in a few cases of typhoidal disease, in which its value seemed to them doubtful. Of patients whose urinary tract was infected with colon bacilli, 11 out of 26 improved under its local and general administration, but only three got rid of their infection altogether. Bacteriophage was also used in the treatment of staphylococcal infections, and particularly for furunculosis, in which A. GRATIA has recorded favourable results. For the latter condition 38 patients were treated, mostly suffering from furunculosis of the external auditory meatus, and the results are claimed to have been "uniformly perfect," the congestion being relieved, the inflammatory swelling subsiding, and the furuncles either aborting or rapidly breaking down and healing. The bacteriophage was administered by subcutaneous injections, and as a rule the condition considerably improved after the second of these. Reaction to the injections was generally slight or absent, but occasionally local and general reactions followed. With other

¹ Bull. de l'Office International d'Hygiène Publique, 1923, **xx**, 1215.

² Presse Méd., August 29th, 1923.

septic infections the treatment did not prove so satisfactory. The investigators insist on the necessity of using strains of bacteriophage of maximal activity, and they suggest that it is more effective in acute than in chronic conditions—a view to which D'HERELLE subscribes in his more recent work.

PULMONARY EMPHYSEMA.

PULMONARY emphysema, first clearly described by Laënnec over a hundred years ago, remains a problem for the pathologist who studies its aetiology and for the clinician who essays its treatment. In the lungs of adults emphysematous islets are sometimes discovered set in the midst of healthy parenchyma. A study of these may throw some light on the pathogenesis of the condition. Thus Letulle,¹ examining the lungs of a young girl, a victim of hereditary syphilis, found minute areas of emphysema surrounding some of the smaller bronchi. Further study showed that such bronchi were affected by an inflammatory process. The airways were blocked with leucocytes, the walls swollen and infiltrated, and the elastic tissue destroyed. Peribronchial inflammation could be seen to extend to the walls of neighbouring alveoli, some of which were thickened by inflammatory products while others were atrophied. These degenerate walls surrounded air spaces which were greatly dilated. In such a case it is easy to understand how a progression of the same process might lead to emphysema of an entire lobule. Is the so-called essential emphysema identical in its origin with that which is associated with and apparently the result of peribronchial inflammation? It was the teaching of Laënnec that emphysema has its origin in a "dry catarrh" involving the bronchi and leading to swelling of the mucous membrane and the formation of thick mucus, and so indirectly to alveolar dilatation. According to this reasoning chronic bronchiolitis is the essential cause of emphysema. Clinical experience suggests that recurrent attacks of bronchial inflammation, often accompanied by bronchial spasm, play an important part in producing the emphysematous lung. Other factors may, however, be involved in its production. As shown above, a peribronchial inflammation due to syphilis may cause localised emphysematous patches in an otherwise healthy lung. A similar process may be responsible for areas of emphysema in the vicinity of tuberculous disease, though a true compensatory hypertrophy is perhaps more commonly found. Laënnec himself remarked that vesicular emphysema often began in infancy. Letulle considers that the absence of anthracosis in emphysematous areas supports this idea and suggests that the origin of the disease should be sought in the infections that attack the lung in early life. The signs of sepsis found in emphysema do not support the theory of inflammation. But this is not the whole story. Despite the extreme frequency of bronchial diseases emphysema is by no means universal. He concludes, therefore, that some congenital deficiency of the lung parenchyma determines the building of the alveolar walls further weakened by inflammation and subjected to the stress of chronic cough.

The changes of an earlier day before the advent of the pathologist were struck by the curious shape of the emphysematous chest. Some 70 years ago Freund propounded the theory that the pulmonary disease was a deformity of the chest wall, the result of disease existing in the chest wall and leading to their restriction. This theory was based on the fact that in all direct and indirect emphysema the chest wall is thickened and the lungs are compressed. The theory of the deformity of the chest wall is based on the fact that in all indirect and indirect emphysema the chest wall is thickened and the lungs are compressed. The theory of the deformity of the chest wall is based on the fact that in all indirect and indirect emphysema the chest wall is thickened and the lungs are compressed.

become permanently distended. The theory has the attractiveness of simplicity, but, unfortunately, it is not in accordance with facts. Chronic emphysema is not uncommon in childhood and may persist through adult life. The condition may be associated with a small and narrow chest as in some forms of senile atrophy. A barrel-shaped chest does not always enclose emphysematous lungs.

On the teaching of Freund the operation of chondrectomy was founded. If the emphysematous lung is the result of a dilated and rigid chest it is reasonable to restore the mobility of the chest wall and to seek to contract its dimensions in order to relieve the over-expanded lung. Hildebrandt was the first operator to apply the teaching of Freund when he performed a chondral resection in 1906, and since that year operations with a similar object have been carried out by a number of continental surgeons. A local anæsthetic is usually employed and the best results are claimed for the evulsion of the costal cartilages of the second ribs together with the perichondral membranes. In some cases the removal of several cartilages is considered necessary. Gerard-Marchant claims that chondrectomy has brought relief to many sufferers and healing to a few. It must be confessed, however, that his statistics are not very convincing. A period of relief is apparently often followed by a relapse, while a post-operative mortality of 15 per cent. proves that the experiment is hazardous. Emphysema is in the main an affection that accompanies the decline of life, when remedies less bold are indicated. The opulent may obtain a measure of relief from winter visits to milder climes, the poor man may still find some comfort in his bottle of medicine. For the adventurous there is an iron chamber in the cellars of Brompton Hospital. The bronchitic and emphysematous can surely dispense with the services of a surgeon.

DR. KINLOCH'S APPOINTMENT.

ON the first day of the New Year the Department of Health for Scotland will take over the powers and duties of the Scottish Board of Health, and its chief medical officer will have powers and duties similar to those of the chief medical officer of the Ministry of Health. Dr. John Parlange Kinloch, who has been appointed by the Secretary of State to hold this position, is a West of Scotland man, who graduated at Glasgow in 1909 and in 1923 succeeded Prof. Matthew Hay as medical officer of health to the city of Aberdeen, and head of the public health department in the University. The output of this department has been very striking, and Dr. Kinloch has shown his capacity to inspire a team of workers in the public health service to produce a remarkable series of valuable contributions to practical problems affecting the health of the community. His great achievement as an administrator has been the unification of the public health and poor-law hospital services of Aberdeen by agreement with the authorities, a change which is entirely on the lines of the hospital developments contemplated in Scotland as the result of the new reforms in local government. The special value of Dr. Kinloch's work has been in concentrating the full force of the official institutions on clinical medicine of every kind. This is the distinctively original note in his work. Incidentally, he has demonstrated the possibilities of co-operation among the public health, poor-law, school health, and local government workers of the city, and of these authorities with the county authorities and with the general practitioners of the north-eastern region. Dr. Kinloch is only 43. He comes to the new department with fully specialised training for the problems now facing the public health service in Scotland. Under the new scheme he will be able to direct the full strength of a large staff of public health officers in every branch of public health.

Annotations.

"Ne quid nims."

BOOKS AS FOMITES.

A REPORT¹ of the Consultative Committee to the Board of Education briefly reopens a subject dealt with in our columns three years ago,² the conveyance of infection through books. Dr. J. E. McCartney then concluded that—with the exception of small-pox—books from public libraries were not to be regarded as dangerous sources of infectious disease. His reasoning was based on the well-known delicacy of most of the organisms conveyed by droplet infection and on the absence of any record of cases infected through the agency of books. The streptococcus is known to survive drying for a short time only, and the unknown viruses of chicken-pox, rubella, and measles are also known to have little viability outside the body. The diphtheria bacillus has greater powers of survival; the membrane kept in the dark was found to contain living organisms several months later, but even this did not convince Dr. McCartney that it would live under the usual conditions in which books are kept. Small-pox, he felt, was in rather a different category. The disease in its severe form is so virulent and serious that no risks can safely be run, and it would be wiser to regard all books and papers as potential dangers if they have been handled by a small-pox patient. The conclusions reached by the advisers of the Board of Education do not differ from those of Dr. McCartney. The pathological laboratory of the Ministry of Health, several county and urban school medical officers, and three medical officers of large public schools contributed evidence, and advised that the risk of conveyance of infection was negligible. A book, they said, could only become infected if actually used by an infected child, and then would be dangerous only for a very short time. Attention had far better be concentrated on articles liable to gross infection, such as towels, handkerchiefs, sucked brushes, and chewed pencils. In the schools of the London County Council books are not disinfected as a routine, although library books from infected homes are usually disinfected by the medical officer of health before return to the school library. There has been much recent evidence and argument to show that room-disinfection, as usually carried out, is entirely futile and, indeed, the report mentions that sterilisation of books by formalin vapour has no value unless every page is closely exposed. Most of the witnesses preferred dry heat, which is liable to warp bindings a little but otherwise does not seriously injure the volumes. The general question is important because if books are, or can be, carriers of virulent organisms they must be responsible for an enormous amount of disease. Often the first thing a sick person demands is an extra supply of books from the library, and few households dream of feeling any responsibility for the infectiveness of the books on return. They may be back in the library less than an hour before they are handed out to some other subscriber who is highly susceptible to the organism in question. It would, however, be difficult to get direct evidence of actual cases of infection arising in this way. So far the evidence is more theoretical than practical, although there is no doubt that most authorities would agree with Dr. J. A. Brincker, principal assistant medical officer in the Public Health Department of the L.C.C., that "dosage, virulence, and susceptibility of the individual are of such great importance in the process of infecting the individual and spreading disease that the importance of spread from school-books recedes almost into insignificance as compared with the more common and important sources of spread."

GLUCOSE IN NORMAL URINE.

THE belief that glucose is a constituent of normal urine, although usually considered heretical, has been expressed from time to time by serious observers, including Pavy. For over thirty years it has been a debatable point. Recently an Egyptian worker, Ali Hassan,¹ has examined in the Faculty of Medicine at Cairo the urine of some 700 Egyptians, mostly students, from 17 to 27 years of age, and has found glucose, in small amounts, in conditions which do not point to abnormal carbohydrate metabolism. He discusses the various tests employed and points out the unsatisfactory character of the yeast fermentation test as usually carried out, especially when the quantity of glucose is very small. The phenylhydrazine test, in which the characteristic osazone is formed, needs care when applied to urine as the crystals are frequently entangled with oily substances which render characterisation difficult. The technique followed by Hassan is as follows:—

25 c.cm. of urine were well mixed with 2 g. of charcoal (Merck's decolorising charcoal was used as a rule) and filtered after standing for 5 minutes. About 15–17 c.cm. of clear colourless filtrate was usually obtained, and to this was added 1 g. of a freshly made mixture of pure phenylhydrazine hydrochloride and sodium acetate (1 phenylhydrazine, 2 acetate, well mixed). The filtrate was placed in a boiling water-bath for 5 minutes, or just until the reagents were dissolved, and then filtered into another tube. The final filtrate was put back into the water-bath for 2 hours; it was then allowed to cool gradually in the bath, and the deposit was examined for crystals after 12–15 hours.

The reaction carried out as above is, the author says, not only sensitive but seldom fails to yield clear and well crystallised osazones, although sometimes yellow oily drops, which can be removed by washing with ether, may separate with the crystals. Normal urine gives mixed crystals of osazones, which Hassan states can be resolved into one identical with glucosazone and another which appears to be the same as Baisch's iso-maltosazone. As we have said, the urine of 700 people was examined, and 20–30 per cent. of the specimens voided 1–2 hours after an ordinary meal yielded typical glucosazone, the percentages being reduced to 12–15 and 7 with specimens voided respectively 4–5 hours and 12 hours after a meal. Experiments on the tolerance to 50 g. of glucose by 28 students showed that this was not necessarily due to abnormal carbohydrate metabolism. The old view that glucose in small quantities is a constituent of normal urine is thus in this investigator's opinion confirmed.

NATIONAL ASSOCIATION FOR COMBATING RHEUMATISM.

WHEN there are already many bodies engaged in the fight with some great national scourge, it is essential that any new organisation should have sufficient prestige and authority to be able to link up the work of the older foundations and to advise them in their activities. It is this need of a central body that led the former British Committee on Rheumatism of the International Society of Medical Hydrology, having dissociated itself from the Society, to propose the formation of a national association to deal with the problem of rheumatism in this country. Similar committees have already been formed in France, Germany, and other countries. A meeting to discuss this proposal was held at the Royal Society of Medicine on Nov. 7th. Sir Thomas Horder, having been elected to the chair, explained the position and emphasised the absolute necessity of constituting a really national body, representing all interests and of high status. He considered that the rheumatic problem in this country had great need of a central body to link up and

strengthen existing efforts such as the Red Cross Clinic, the British Medical Association committee and the work carried on at the spas, as well as the activities of the Ministry of Health, which were described to the meeting by Dr. J. A. Glover. Already we have in London 230 beds allocated by the public authority for rheumatism and chorea, and 350 more are to be provided. The three rheumatism centres of the London County Council and the rheumatism clinics of Paddington and Kensington boroughs are doing excellent work, and indeed for acute rheumatism the public authorities are doing far more than they are for that bugbear of all concerned, chronic rheumatism. Nevertheless, the valuable reports of the Ministry of Health Office Committee and of the Medical Research Council have served to draw attention to the serious medical and economic problem. As Dr. Fortescue Fox observed, no group of diseases, save perhaps the tropical, is so disastrous to the public health and prosperity.

The meeting unanimously approved of the motion of Mr. W. A. Appleton (General Federation of Trades Unions) and Dr. C. W. Buckley, that a National Association should be constituted. After a little discussion of detail it was decided that the Association should have a Council representing all the various interests concerned and an executive committee of 12. The nucleus of this committee was elected at the meeting, the Chairman, Dr. Fortescue Fox, Dr. Kerr Pringle, Dr. Buckley, and Mr. Appleton being appointed, with power to co-opt. Dr. M. B. Ray will act as secretary pro tem. There are to be a number of standing committees, including the following: General purposes, Medical, Finance, Industrial, Approved societies, Administrative, Research. Dr. Morley Fletcher proposed, and Mr. H. Lesser seconded, that membership of the Association be open to all on payment of an annual subscription, and that members be entitled to attend and take part in an annual conference as well as other general or extraordinary meetings and to receive any publications issued by or on behalf of the Association. On the motion of Mr. P. Rockliff and Dr. W. Edgecombe, it was agreed to hold an annual conference for papers and discussions, the proceedings to be printed and circulated to all members.

"ENDOGENOUS" CYANOSIS.

ONE by one the abnormal conditions of urine formerly classed as "endogenous" or "essential" are being removed from that group as their aetiology is discovered. An interesting example is reported in Guy's Hospital Reports, July, 1928 (p. 275), by Dr. M. O. Raven, whose patient, a middle-aged lady who had suffered from many diseases and undergone many operations, was found suffering from pyrexia, hæmaturia, and marked cyanosis. On spectroscopic examination the blood showed the bands of methæmoglobin. This discovery was followed by a very full examination of the patient by Dr. A. F. Hurst; the conclusion was reached that the patient was suffering from a colonic infection. A colectomy was performed and the patient thereafter irrigated the lower bowel through the opening with 20 pints of water daily for some weeks, during which she improved not at all and continued to live in a pitiable state of ill-health. Not long after, when the patient had returned home, she was accidentally found to be taking very large quantities of antikamnia, a preparation that contains 70 per cent. of acetanilide. As soon as this habit of drug-taking was stopped the cyanosis disappeared not to return, though the kidneys had evidently been permanently damaged by the passage of abnormal blood-pigments over a long period of time. Dr. Raven remarks that during the war individuals anxious to escape military service were sometimes found by examining boards to be taking overdoses of phenacetin. Dr. J. A. Ryb adds a note to Dr. Raven's communication, stating that for some time he has been becoming increasingly suspicious that cases of so-called endogenous cyanosis are in reality due to drug-addiction, most of the

patients with this rare complaint known to him having had peculiar psychological characteristics. Dr. Raven's case confirms this view and he points out that before declaring any case of methæmoglobinæmia with cyanosis to be of endogenous origin, it is necessary to exclude the taking of drugs of the acetanilide group. Indeed, he goes further and is inclined to doubt the existence of enterogenous cyanosis altogether. Cases of methæmoglobinæmia are so rare that it is unlikely that any single observer could decide the question; cases of microbic cyanosis have been described in some detail, but in the absence of any suspicion of the connexion no rigid exclusion of drug-addiction has been made. A well-organised collection of cases of endogenous cyanosis throughout the country and an impartial inquiry into their history and clinical condition would be required before a decision could be arrived at. In the meantime it must be remembered that other drugs besides those of the acetanilide group, especially potassium chlorate, carbon monoxide, sulphuretted hydrogen, sulphonal, and trional are capable of causing a chronic cyanosis. On the other hand, such rare diseases as Winckle's disease (epidemic hæmoglobinuria in the new-born), in which methæmoglobinæmia undoubtedly occurs, render it quite possible that corresponding changes in blood-pigment may occur in the adult as a result of infection.

ACCOMMODATION FOR THE SICK IN PUBLIC SCHOOLS.

A MEMORANDUM¹ on the accommodation for the sick in public schools has been published by the Ministry of Health, based upon an inquiry conducted at a considerable number of well-known public schools in England. The memorandum puts forward various recommendations which Sir George Newman hopes may be of some practical use to the governing bodies of the schools, to the masters and parents, and to school medical officers. The provision for the sick was found adequate as a rule to deal with ordinary trivial illness and mild infectious diseases in some schools, and with almost any sickness except large epidemics of infectious disease in others. The different types of accommodation provided included (a) house sick-rooms, (b) a sick-house, (c) an infirmary, (d) a sanatorium. The house sick-rooms were usually utilised for minor illnesses, but in some schools this accommodation had to deal with all cases of sickness other than infectious or major surgical cases. The house sick-rooms were usually near the quarters of the house matrons, and were of greatest use in those schools where the medical officer gave only part time to this work; in those schools where the medical officer was on a whole-time basis, the boys were usually transferred, when sick, to the sick-house, infirmary, or sanatorium. Great differences were found between the sick accommodation of various kinds provided at different schools; many schools having ample, others negligible, accommodation. The sick-house was, as a rule, a building intended for the reception of all non-infectious cases and often replaced house sick-rooms. An out-patient department and sometimes an operating theatre and an X ray room were occasionally included in the sick-house, which house was usually centrally situated. The infirmary was found to be a building intended for the accommodation of all kinds of sickness, whether medical, surgical, infectious, or non-infectious, including an out-patient department, all under the care of a medical officer. It was usually situated away from the school buildings. As regards emergency accommodation for epidemics of infectious disease, it was found that in some schools no prearranged plan existed for dealing with such an emergency, while in others, dormitories and large class-rooms could be quickly converted into

¹ A Memorandum on the Accommodation for the Sick provided at certain Public Schools for Boys in England. By Capt. W. D. Gwynne, M.C., M.B., Ministry of Health, London: H.M. Stationery Office, 1928. Pp. 25. 1s.

wards, and some class-rooms were even specially planned so as to be used for this purpose if necessary. It was found that in many schools no adequate facilities existed for the proper isolation of doubtful cases of infectious disease, such as separate sanitary arrangements in the sanatorium. Quite modern buildings often contained a quite inadequate number of sanitary conveniences.

The second part deals with the principles which should guide schools in providing new accommodation or extending that which already exists, and the minimum standards to which such provisions should attain. The memorandum makes the following suggestions as to the proportion of sick-beds to boy population: (a) The total number of sick-beds—including those in house sick-rooms, sick-house, infirmary, and sanatorium—should not, as a rule, be less than 18 per cent. of the total boy accommodation; (b) house sick-rooms are regarded as essential except for schools which are so centralised that arrangements can be made for immediate removal of boys to infirmary, sick-house, or sanatorium at any hour of the day or night. The minimum ration of beds in house sick-rooms should be 6 per cent. of the boys in the school; (c) the total number of beds outside the school-houses, in the infirmary or sanatorium, should be 12 per cent.; (d) the number of beds for non-infectious patients, excluding those provided in separate school-houses, should be 2.5 per cent. of the population; (e) infectious beds to cope with small epidemics should be provided, the suggested proportion being 9.5 per cent. of the population.

The memorandum goes on to consider many other important points, such as the position and site and disposition of the buildings, and the actual accommodation for the patients. The types of wards needed for infectious and non-infectious cases are also discussed. Bed space, sufficient for non-infectious cases, can be adapted to infectious cases if necessary, either by spacing out the beds or by leaving an empty bed between every two patients. The provision of suitable dayrooms for convalescent boys in the hospital block is advised and also sanitary annexes, duty rooms for the nursing staff, and adequate suitable accommodation for the nursing and domestic staff. In the last section of the memorandum the construction of the hospital or sanatorium is considered in detail, and useful suggestions are made as regards heating, lighting, and sanitary arrangements. It is a little remarkable that no mention is made of the use of any available accommodation in neighbouring isolation hospitals; nor is there any pronouncement as to preventive measures which might in the future affect the number of beds required for infectious cases such as diphtheria and scarlet fever. No doubt the time will come when many more diseases will be wiped out by preventive and sanitary measures. Even now, such diseases as diphtheria, scarlet fever, small-pox, and to a great extent also enteric fever, could be prevented. Apart from specific measures, it might be emphasised that if boys are taught to live in the open air by day and to sleep as nearly as possible in the open air by night, there is far less chance of infection by microbic diseases.

INJURY AND INFECTION.

It has long been recognised that local injury of tissues often determines the site at which microbes circulating in the blood stream settle down and produce their characteristic lesions. The clinical connexion between injury of bones and acute osteomyelitis or tuberculosis is well known; experimentally *Bacillus welchii* and the tubercle bacillus may be localised by injections of calcium salts or silica. The skin lesions of many non-bacterial diseases (syphilis, small-pox, vaccinia, foot-and-mouth disease, chicken-pox, and measles) are influenced by trauma or irritation in the same way; so is the active agent of the Rous sarcoma. Sir Thomas Lewis and his co-workers have lately shown that all forms of injury of the skin lead to the local liberation of

histamine (or near-histamine), which causes a local vaso-dilatation and an increase in capillary permeability, and the same thing probably happens in all tissues. It has occurred to Dr. G. M. Findlay¹ that these facts may afford an explanation of the relation between infection and injury, and in a series of elegant experiments he makes out a good case for his suggestion. A rabbit was injected intravenously with a culture of *Staphylococcus aureus* and then 0.02 c.cm. of histamine solution was injected intradermally into the right flank and 0.02 c.cm. of phosphate buffer solution into the skin of the left flank; these injections were repeated hourly for three hours. Twenty-four hours later the area which had received histamine was inflamed, and during the following days the lesion developed into abscess formation with sloughing of the skin; abundant staphylococci were found microscopically and recovered in culture. The site of the control injections showed no obvious change and nothing more than a transient excess of leucocytes could be found histologically. Experiments along these lines were also made with *Streptococcus hæmolyticus*, a pneumococcus, and the viruses of fowl-pox, vaccinia, and the Rous sarcoma, and in each case histamine was effective in localising a generalised infection. Whether the vascular dilatation or the increased stickiness and permeability of the capillary wall is the more important factor in producing this result is uncertain. Perhaps both are effective.

AN EMERGENCY OF CHILDHOOD.

UNDER the name of acute laryngo-tracheobronchitis Dr. H. L. Baum, of Denver, describes² a severe form of acute inflammation of the upper air passages, in which the symptoms are such as to require the introduction of a tube to prevent asphyxiation. The condition, though rare, is, of course, not unknown, being usually classified under the heading of cedematous laryngitis; but Dr. Baum has rendered good service in calling attention to its characteristics, for it is a very serious affection and one in which prompt recognition and treatment may save a life. The disease occurs almost exclusively in children; of Dr. Baum's 24 cases the oldest was 9 years, and 15 were under 3 years of age. It usually develops in the course of an acute infection of the respiratory tract, the onset being that of an acute cold with rhinitis and pharyngitis, and it is most common during the seasonal epidemics. The signs are embarrassment of respiration, retraction in the epigastric, suprasternal, and supraclavicular regions, and cyanosis. The respiratory obstruction is due to subglottic cedema, and Dr. Baum makes the important point that there is seldom any marked swelling of the larynx above the glottis. He also lays stress on a fact of great importance, not only in this affection, but in all forms of obstruction of the upper air passages in young children—namely, that from this obstruction they are subjected to the most severe physical strain imaginable, which throws a terrific burden on the heart. The result is that the cyanosis is of a characteristic pale character, and that the patient is not so much blue as white. In this condition, therefore, as in all forms of laryngeal obstruction, the urgent indication is to restore the airway without delay. A comparatively low temperature is characteristic of this exhaustion from dyspnoea, and it frequently rises to 104° or even 105° F. after tracheotomy has been performed. In his earlier cases Dr. Baum always performed tracheotomy, but he found that plugs of inspissated mucus subsequently formed in a number of cases and blocked the trachea and large bronchi; they were often removed with success through the bronchoscope, but his experience is that they are less liable to occur after intubation, which he now prefers in the treatment of these cases. Steam did not appear to prevent the formation of the plugs. Even after relief of the respiratory obstruction, the prognosis is still extremely grave, for the infection is

¹ Jour. Path. Bact., 1928, xxxi., 633.

² Jour. Amer. Med. Assoc., Oct. 13th, 1927.

a virulent one, and pneumonia often develops. This may be either lobar or broncho-pneumonic in type and it is the commonest cause of death, accounting for nine of the ten deaths in Dr. Baum's series of 24 cases.

A PATHOLOGICAL LABORATORY FOR THE CUMBERLAND INFIRMARY.

AFTER prolonged negotiations a proposal to build and equip a pathological department at the Cumberland Infirmary, Carlisle, was adopted at a special meeting of the committee of management held on Nov. 5th, and the subcommittee which had drafted the proposal was reappointed to carry it into effect. The report which led to this welcome decision indicated how the work of a hospital with 379 beds was being hindered by the want of such a department. Examples were given of the function of such a laboratory in the diagnosis of diphtheria by laboratory methods, in the determination of the type of organism in (say) cerebro-spinal fever, without which the appropriate serum could not be determined and administered, in reducing the risks of operation on the eye by preliminary bacteriological investigation, in the preparation of vaccines from the organism actually causing the disease, and in the diagnosis of new growths by personal collaboration between clinician and pathologist. The proposal includes the engagement of a fully qualified whole-time pathologist, with a qualified technical assistant and a laboratory boy to assist him, the work to be classified under the three headings of bacteriological, histological, and biochemical. The sum of £3000 is suggested as the cost of the building with its initial equipment, and considerable return of revenue is anticipated from the fees in respect of outside work from public authorities. The capital cost of the building being already provided for by funds in hand or promised for the purpose, only the annual cost, estimated at £800 per annum during the first few years, will fall on the hospital budget. The work is to be put in hand at the earliest possible date, with a view to having the department in full operation at the official opening of the new hospital wards. The hope is expressed that in the course of time the Cumberland Infirmary will become a recognised centre of clinical research.

AN INTENSIVE CANCER CAMPAIGN.

A CAMPAIGN against cancer, organised jointly last April by the Committee on Cancer of the Massachusetts Medical Society, the Massachusetts Branch of the American Society for the Control of Cancer, and the State Department of Public Health, has provided instructive material for students and critics of educational health movements. According to the report of Dr. F. G. Balch, Dr. G. H. Bigelow, and Dr. R. B. Greenough,¹ the plans for this campaign included a mass meeting in each city in which there was a State-aided cancer clinic, a request to each of the 18 district medical societies to hold a special meeting to consider cancer control, an information bureau, and press, poster, cinema, and wireless publicity. A letter was addressed to the clergy, asking for a pulpit announcement of the campaign on Sunday, April 22nd. Fifty-seven speakers, primed with facts and theories about cancer, addressed 129 groups, or an approximate total of about 12,000 persons. Among the speakers were the Governor and Mayor of Boston. To elicit expert opinions on the results of this campaign, a questionnaire was sent to all the physicians in Massachusetts asking for: (1) the number of people with cancer who sought advice during May as a result of it; (2) the number without cancer but with some definite disease who sought advice under the same conditions; (3) the number without cancer or other disease who sought advice; and (4) the opinion of the physicians of the value of such campaigns. About 25 per cent. (1179) of the Massa-

chusetts physicians responded. They had examined 3086 persons as a result of the campaign, and had found 438, or 14 per cent., to be suffering from cancer. These figures did not include the persons who attended cancer clinics. An opinion as to the value of the campaign was expressed by 1132 physicians, of whom 26 considered the campaign as of no value, 38 as harmful, whilst 108 were doubtful. The remaining 960, or 84.7 per cent., thought it was worth while. The number of cases of cancer seen in the clinics rose during the campaign, and fell rapidly afterwards. The percentage of operable cases was not, however, altered appreciably—a fact which suggests that cancer-phobia was not markedly increased. Besides the 438 persons with cancer, there were 1427 who sought advice as a result of the campaign, and who were found to be suffering from some disease other than cancer. For every person visiting a cancer clinic, there were approximately 22 who consulted practitioners privately.

THE SECRETS OF THE OVARY AND OF THE PITUITARY BODY.

NOTHING is more encouraging in modern medicine than the speed with which new discoveries are being made available for trial at the bedside. It is happily in the interests of the manufacturing chemists to pounce quickly on any line of inquiry that may enable them to market an effective drug or prepare a potent extract in advance of their fellows, and the competition between them has resulted in the establishment of many research laboratories whose commercial origin serves only to lend a practical bias to the work carried on and not at all to affect its high quality. It was from the laboratories of Parke, Davis and Co., for example, that Oliver Kamm and four colleagues described early in this year² the separation of two extracts in the posterior lobe of the pituitary body, the one having oxytocic power (the power to stimulate the musculature of the uterus), and the other having the pressor property. Working at the Wellcome Physiological Research Laboratory at Beckenham, J. H. Gaddum³ has confirmed the work, which was considered in April last by the Permanent Commission of the Health Organisation of the League of Nations which deals with the standardisation of sera, serological reactions, and biological products. Fortunately for convenience in standardisation, the oxytocic and pressor activities seem to vary together in any batch of material. For the purposes of biological assay the test on the isolated uterus of the virgin guinea-pig, described in the United States Pharmacopœia, Edition X., is recommended by the Commission for estimation of the oxytocic activity, while for estimation of the pressor activity comparative tests on the anaesthetised dog or the decapitated cat are recommended; in practice the discoverers of the method of separating the two principles have found no difficulty in expressing the activity of their univalent preparations in pressor and oxytocic units of 0.5 mg. of the international standard powder. It remains to be considered whether the antidiuretic action of pituitary extract is not yet due to a third principle, whose activity may or may not be expressible in antidiuretic units of the standard powder.

The clinical importance of the separation of these principles is emphasised in THE LANCET of Oct. 6th, 1928 (p. 691), by Mr. Aleck Bourne and Dr. J. H. Burn. They confirmed by direct observation on the human subject that fact that the pituitary principle which acts on the parturient uterus is identical with that which Kamm and his co-workers found to stimulate the non-pregnant guinea-pig uterus, and they also noted that vasopressin, even in large doses, has little if any effect on the uterus in labour. In fact, they found no difference between the action of oxytocin and that of pituitary extract on the uterus, and point out that the use of the former has the

¹ New England Jour. Med., August 24th, 1924.

² Jour. Amer. Chem. Soc., 1928, L., 573.
³ Jour. Phys., 1928, Lxxv, 151.

advantage of precluding the possibility of pituitary shock, for it is to the vasomotor effects of the extract that collapse (rarely but serious when it occurs) has been attributed. On another page of this issue of THE LANCET Mr. Bourne and Dr. Burn record some further observations, this time on animals, which suggest that the mode of action of pituitary extract on the parturient uterus may be even more complicated than has been supposed, and may depend partly at least on the synergistic action of oestrin. The isolated uterus of a guinea-pig was put in a bath of 100 c.cm. of Ringer's solution and treated with sufficient pituitary extract to produce a small contraction. The solution was then changed, to remove the pituitary extract, and a dose of 0.05 units of oestrin was added to the bath and allowed to remain for 6 minutes. At the end of this time the same dose of pituitary extract (0.01 units) was added but now the contraction was very much greater than that previously recorded. Later the solution was again changed and after complete relaxation had been established it was observed that the addition of pituitary extract alone produced only the very small contraction first recorded. In order to test the specificity of effect a corresponding experiment was carried out using histamine instead of pituitary extract, with negative results. The fact that this relationship between oestrin and pituitary extract is specific suggests to the authors that the phenomenon is one of physiological importance, though they admit that only clinical investigation can decide to what extent the sensitiveness of the uterus to pituitary extract can be enhanced by the use of oestrin.

It would be tempting, but probably at this stage quite unjustifiable, to attempt to correlate this work with that on the new tests for pregnancy which we surveyed recently.³ The urine of pregnant women near term contains a large quantity of oestrin, as does also the placenta. According to B. Zondek and S. Aschheim the ovarian hormone is accompanied by the hormone from the anterior part of the pituitary gland, which latter they regard as the activating factor. It is evident that the interaction of the secretions from the ductless glands are exceedingly complex and it seems possible that the functions of the two parts of the pituitary may after all have something in common.

THE poll for elected members of the Dental Board established under the provisions of the Dentists Act, 1928, of the Irish Free State, was held last week. Of dentists registered otherwise than under Section 3 of the Dentists Act, 1921, the following were elected: Messrs. J. E. Hogan, K. McGrath, J. I. Potter, and K. E. O'Duffy. Of dentists registered under Section 3 of the Dentists Act, 1921, the following were elected: Messrs. A. J. McGinty and G. C. Johnston. The Board is now complete.

THE Royal Dental Hospital is to be congratulated on having decided to establish a department of electrotherapeutics for the treatment of dental disease, to which Mr. F. Talbot, who has devoted much attention to the application of ultra-violet radiation to dental conditions, has been appointed. This is a wise step, for while there seems little doubt that electrotherapy and ultra-violet rays may be usefully employed in dental disease there is still much to be learned about the scope and limitations of these newer forms of treatment, and the establishment of such a department as part of a dental hospital offers an opportunity for careful clinical investigation.

WIMBLEDON HOSPITAL. — Prince and Princess Arthur of Connaught will visit this hospital on Wednesday, Nov. 21st, at 3 P.M., when Princess Arthur will open the new children's wing.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XI.—THE ARNETH OR POLYNUCLEAR COUNT.

By W. E. COOKE, M.D. LIVERP., M.R.C.P. LOND.,
PATHOLOGIST AND BACTERIOLOGIST, WIGAN INFIRMARY.

IN the Arneth or polynuclear count the polymorphs are separated into five classes according to the number of their nuclear segments. Cells with undivided nuclei are placed in Class 1, those with two lobes in Class 2, and so on to Class 5. Polymorphs with more than five nuclear segments are so rare in normal blood that when they do occur they are placed in Class 5.

The Count in Health.

The length of life of the polymorph in the blood stream is about three weeks. It enters the circulation from the marrow as a Class 1 cell with a single lobed nucleus, and as the cell grows older the nucleus becomes more segmented. The average normal count, that is, the percentage in the various classes, is:—

(1)	(2)	(3)	(4)	(5)
10	25	47	16	2

This is subject to slight individual variations, but a count with more than 40 in Classes 1 and 2, the left-hand columns, should be considered abnormal. These figures represent a polymorph population comparable to infants, children, men, old men, and senile men, in which the deaths in the older groups are exactly compensated for by the births from the marrow. The figures of the polynuclear count tell us whenever this normal state becomes altered, whether by the addition of an unusually large number of young cells, by the removal of an unusually large number of old cells, by both these conditions combined, or by some interference with the normal development.

The Count in Disease.

In all cases of microbic infection there is an increase in the percentage of the younger cells of Classes 1 and 2, and a diminution in Classes 3, 4, and 5, and the count has, in Arneth's words, a left-handed drift. This is true, whether the total polymorphs remain normal in numbers, whether there is a polymorphic leucocytosis, or whether there is a polymorphic leucopenia. This last condition—increased activity of the marrow with diminution of the total number of polymorphs in the circulation—appears paradoxical, but obtains in all infections where there is a leucopenia. Any increase in the cells of Classes 1 and 2 above 40 indicates toxæmia. The amount of the deflection depends upon the severity of the toxæmia and the amount of consequent marrow reaction. The count, therefore, should be deflected less in cases with a small local infection such as early laryngeal tuberculosis, dental sepsis, and duodenal ulcer, than with a general infection such as pneumonia, or where the absorptive area is large as in advanced pulmonary tuberculosis. This is, in fact, found in practice.

The Count in Diagnosis.

Bearing the above facts in mind, it will be apparent that the count, by the confirmation of the presence or the absence of infection, can be of great assistance in diagnosis. This is exemplified in the following case:—

W. H., aged 24 years, gave the history of having had "sciatica" in both legs three months previously. This was relieved by aspirin but left his legs somewhat weak after walking. Otherwise, he said he was quite well and thought of resuming work. Clinical examination revealed nothing, except that the left knee-jerk was difficult to

elicit. The eleventh thoracic spine was somewhat more prominent than normal but there was no tenderness on percussion nor on hyperextension of the spine.

A blood film was taken as a matter of routine and showed the following:—

Differential count (per cent.): polymorphs, 44; lymphocytes, 40; monocytes, 13; eosinophils, 2; plasma cells, 1. Polynuclear count:—

(1)	(2)	(3)	(4)	(5)
42	40	18	0	0

The fact that the polynuclear count showed a marked left-handed deflection indicated that there was a source of infection of considerable activity and led to further investigation at once. X ray examination revealed tuberculous disease of the body of the eleventh thoracic vertebra.

The following is an example of infection suspected but proved not to be present:—

B. L., aged 12½ years, complained of pain and tenderness in the right iliac fossa simulating appendicitis. The polynuclear count was:—

(1)	(2)	(3)	(4)	(5)
11	31	43	14	1

This excluded any possibility of acute appendicitis.

That these cases are not exceptional, anyone using the count as part of routine clinical examinations can testify.

The Count in Prognosis.

The length of life of the polymorph being 21 days, it is obvious that once the polynuclear count has become deflected by an infection, the minimum time for its return to normal will be three weeks. In diseases as diphtheria in which the toxin can be neutralised at once, the count occasionally returns in that time to normal, but in most infections the return is gradual and may take 6 to 12 weeks or longer. If the patient is recovering the count will show a lessened left-handed drift on repeated examinations, but if any complication arises, there will be a check in the right-handed movement and a further increase in Classes 1 and 2.

N. C. had an infection of the patellar bursa, lymphangitis, and lymphadenitis of the glands in Scarpa's triangle. The bursa was opened on Oct. 13th, 1926. Her counts were as follows:—

Date.	(1)	(2)	(3)	(4)	(5)
Oct. 13th, 1926	46	32	21	1	0
" 21st, "	33	41	25	1	0
Nov. 3rd, "	18	42	32	8	0

Nov. 4th:	Rigor,	temperature	of	100° F.,	acute tonsillitis.
Nov. 5th, 1926	55	30	15	0	0
" 12th, "	40	46	12	2	0
" 19th, "	22	42	32	4	0
Dec. 3rd, "	12	38	38	12	0
Jan. 5th, 1927	10	22	40	18	4

As a guide to the effect of treatment, for instance, the removal of a focus of infection, the following example may be quoted. The first count was taken before an operation for removal of infected tonsils and adenoids, which took place on the same day.

Date.	(1)	(2)	(3)	(4)	(5)
Jan. 23rd, 1924	25	36	36	3	0
Mar. 14th, "	8	28	41	18	2

The Count in Addison's Anæmia.

As mentioned above, polymorphs with more than five nuclear segments are rare in normal blood. In Addison's anæmia polymorphs with hypersegmented nuclei are frequent, and in many of these cases the count is actually right-handed. Large numbers of cells showing six, seven, or as many as ten nuclear segments are present. These are placed in Class 5. Typical counts are as follows:—

(1)	(2)	(3)	(4)	(5)
5	20	39	39	11
5	16	29	39	9
16	22	32	16	14
10	15	28	24	13
6	20	42	20	12

Occasionally, a count in pernicious anæmia shows the curious state of being left-handed, but at the same time having a large percentage of polymorphs with five or more segments as in the following:—

(1)	(2)	(3)	(4)	(5)
20	31	17	16	16

The explanation of this is obscure, but one may conclude that in this disease there is some interference with the normal development, either by inherited defect from its marrow parent, or by the presence of some substance in the plasma that prematurely ages the polymorph, or by dysfunction of the physiological mechanism which is responsible for the destruction and elimination of aged leucocytes.

Surg. Comdrs. J. E. Johnston and R. Willan are placed on the Retd. List with the rank of Surg. Capt.

Surg. Lt.-Comdr. F. H. Vey to be Surg. Comdr.

Surg. Lts. H. J. McCann to *Montrose*, and D. L. Pow to *Rosemary*, on commg.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt. C. C. Elliott to be Surg. Lt. Comdr.

ROYAL ARMY MEDICAL CORPS.

The undermentioned Capt. to be Maj.: F. G. L. Dawson, W. S. Martin, G. B. Hadden, C. M. Forster, C. F. Anthonisz, J. T. McConkey, F. R. H. Mollan, G. O. F. Alley, W. H. A. D. Sutton, A. R. Oram, G. T. Gimlette, C. H. C. Byrne, T. E. B. Beatty, C. O. J. Young, J. Bennet, J. C. Preston, and J. V. McNally.

P. D. Johnson to be Temp. Lt.

D. C. McC. Ettles to be Lt. on prob.

TERRITORIAL ARMY.

J. V. Morris to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Capt. J. L. Johnston from the Active List to be Capt.

INDIAN MEDICAL SERVICE.

Debi Prosad Mitra and Tulsi Das to be Temp. Lts. T./Lt. Sangham Lal relinquishes his temp. commn.

COLONIAL MEDICAL SERVICES.

The following appointments have been made by the Secretary of State for the Colonies: Dr. D. B. Wilson, Dr. K. Edmundson, and Dr. F. V. Adams, Medical Officers, Tanganyika Territory; Dr. R. S. F. Hennessy and Dr. J. S. Brown, Medical Officers, Uganda; Dr. A. J. W. Wilkins, Medical Officer, Kenya; Dr. S. Batchelor, Medical Officer, and Miss W. D. Cargill, Lady Medical Officer, Gold Coast; Miss E. M. Turner, Medical Inspector of Schools, Federated Malay States; Dr. L. A. P. Slinger, District Medical Officer, St. Lucia; Dr. D. B. Smith, Medical Officer, Straits Settlements; Mr. J. I. Moir, Colonial Surgeon, Falkland Islands; Captain W. Foskett, Medical Officer, Fiji; and Mr. D. C. Bell, Medical Officer, West African Medical Staff (Colony not allocated).

DEATHS IN THE SERVICES.

The death was announced last week of Major-General John Blackburn Smith, C.B., C.I.E., I.M.S., retired, President of the Medical Board at the India Office and Medical Advisor to the Secretary of State for India. He was the son of the Rev. J. A. Smith, of Cork, and was born on Jan. 21st, 1855. He received his medical education at Queen's College, Cork, and graduated in medicine and surgery at the Royal University of Ireland in 1887. Two years later he obtained his first commission in the Indian Medical Service, and was in military employ till 1891, when he was appointed civil surgeon in the Bombay Presidency, and served at various stations there. He was A.D.M.S. of the Poona Division, D.D.M.S. of the Eastern Command in India, and was an hon. surgeon to the Viceroy. For his services during the European war he was mentioned in despatches, awarded the C.B. in 1918, when he became hon. physician to the King, and the C.I.E. in 1922. General Smith married in 1890, Lady Mayne, daughter of the late W. R. Nelson, of B. East, by whom he had three sons and one daughter.

Special Articles.

THE UNIVERSITY OF LONDON: THE NEW STATUTES.

By PERCY M. WALLACE, M.A. OXF.

I.*

To the issues of THE LANCET of September 24th and October 1st, 1927, I contributed two articles, in which I dealt respectively with the constitution and machinery provided for the University of London in 1900 by the Commissioners appointed by the Act of 1898, and with the administration by the new Senate of the organisation thus committed to their charge, including the developments which they had themselves initiated and carried out within the terms of the Statutes—occasionally amended, as need arose—under which they worked.

I have now to bring the story up to date by indicating the general character of the new Statutes which have recently been promulgated by another body of Commissioners appointed by a later Act of 1926. Before, however, proceeding to summarise this latest instrument, it appears due to all the parties, and to the situation generally, to refer briefly to successive steps taken in the interval between those dates—if only to show how intense and prolonged has been the effort made to supply London with a University adequate to her complex requirements. For within less than nine years of the reconstruction of which I gave an account in the first of my earlier articles some dissatisfaction—not so much with the actual operations of the Senate as with the conditions imposed on those operations—had begun to demand a radical revision of the new constitution.

To the general public, unable to appreciate the peculiar delicacies and complications involved, it may appear strange—it may even be regarded as in some degree a reflection on the earlier Commissioners or on the Senate (or on both bodies)—that machinery so laboriously constructed should within so short a space have been considered to require so extensive an overhaul. But this is not a complete or even an equitable statement of the case. To those who had been concerned with the daily administration of the new system the need for further reform was not evident—at any rate it did not appear urgent. Indeed, looking back, as we can now do, over nearly twenty years' further record, we may regard it as a remarkable tribute to the insight of the Commissioners of 1898 that out of the confusion and conflict of that date they should have proved themselves able to devise—almost *de novo* as far as their chief problem was concerned—a constitution which has in the main continued down to the present year to display an unflinching and fruitful vitality. The developments which the Senate, always alert and always cautious, have under the now moribund dispensation achieved, both in the scope of their operations and in the efficiency of their methods, have for the most part and in all essential respects been conducted along the lines laid down in the Statutes of 1900; and such amendments of this governing code as have from time to time been found technically necessary for the regularisation of their projects have in almost every case been amendments in the strict sense—not rescissions or fundamental alterations, but natural and organic expansions or adjustments which the original authors would certainly have gladly incorporated in their text had the conditions which called them forth been operative at that date.¹

But, although the Commissioners of 1898 may, as we now recognise, be justly and frankly credited with having constructed better than they themselves could have known, and though the evolution of the re-organised University proceeded generally with a smoothness that only devotion and good will could have won from apparently so cumbrous a machine, it became gradually evident that in Government quarters there was a considerable degree of discontent with what was regarded as the slowness of the rate of practical progress. This opinion, I repeat, was not shared to any notable extent by those actually engaged upon the detailed administration of the organism, whether concerned specially with the Internal or the External interests or not affected by any strong party bias. The general view of the Senate was that they had accepted the new constitution, that they appreciated its various bearings and the difficulties involved in its practical operation, and that they could be trusted, if left alone, to carry out their duties fully and fairly for the benefit of all classes. But the higher authority prevailed, and on February 24th, 1909, a Royal Commission was appointed, with Mr. (the late Lord) Haldane as Chairman,

"to inquire into the working of the present organisation of the University of London, and into other facilities for advanced education (general, professional, and technical) existing in London for persons of either sex above secondary school age; to consider what provision should exist in the Metropolis for University teaching and research; to make recommendations as to the relations which should in consequence subsist between the University of London, its incorporated Colleges, the Imperial College of Science and Technology, the other Schools of the University, and the various public institutions and bodies concerned; and further to recommend as to any changes of constitution and organisation which appear desirable; regard being had to the facilities for education and research which the Metropolis should afford for specialist and advanced students in connection with the provision existing in other parts of the United Kingdom and of Our Dominions beyond the Seas."

This Commission, having in the course of the next four years issued an Interim Report and four bulky volumes of evidence taken from a vast number of witnesses, submitted their Final Report on March 27th, 1913. They commenced by emphasising their deliberate conviction that the University as then organised was "fundamentally defective," and proceeded to develop an almost entirely new constitution, of an even more complicated character than that which they desired to supplant. There was to be a new body, a "Court," of "about 200" members, in supreme control, with a Senate, of 15, as the executive; the Academic Council, of about 20 members, would be in the main confined to limited advisory functions; there would be a new "Committee for Technology," with wide executive and financial authority; to the Faculties would be entrusted very extensive powers and duties; and the status of Professors, Readers, and other Teachers respectively, and the position in the general system to be held by Colleges, Departments, and Schools, would be considerably (in some cases very greatly) affected either by enlargement or by diminution—these and numerous other provisions being set out at laborious length and in precise detail. Fortunately, we are not concerned with the *minutiae*—or even with the general outlines—of this prodigious scheme, which cannot be regarded as in any vital sense the basis of the Statutes just promulgated. For, though a Departmental Committee of the Board of Education was appointed five months later to consider what steps could best be taken to carry it into effect, the outbreak of the War in the following year put a stop to its labours, and the long period of efforts towards national recovery and reconstruction that followed the signature of Peace did nothing to encourage their revival. And when, on October 8th, 1924, the President of the Board appointed a new Departmental

* Part II. will appear in the next issue of THE LANCET.

¹ In confirmation of this view I may mention that on no occasion since 1900 has the Privy Council refused its assent to any amendment submitted by the Senate.

Committee, with Lord Ernle as Chairman, it was with a reference couched in significantly cautious terms:—

"To consider the Final Report of the Royal Commission on University Education in London dated the 27th March, 1913, and, having regard to present circumstances and after consultation with the persons and bodies concerned, to indicate what are the principal changes now most needed in the existing constitution of the University of London and on what basis a Statutory Commission should be set up to frame new Statutes for the University."

This body, to the Chairmanship of which Mr. (now Sir) Hilton Young had been, in February, 1925, appointed on Lord Ernle's resignation through ill-health, issued their Report in March, 1926.⁴ They prefixed to their constructive comments a declaration as follows:—

"A careful examination of the Haldane Report and the knowledge which we have acquired of the progress and development of the University, particularly since the war, have led us to the conclusion that it would now be impractical to attempt to give effect to some of the major recommendations of the Commissioners. There are other recommendations which require modification to meet altered circumstances, and there are others, again, which the University has already substantially adopted."

Of the idealism of the Commissioners, and of their "careful and comprehensive analysis of constitutional problems," they spoke with admiration and gratitude. "But," they added,

"we consider our terms of reference as conferring on us the duty of devising an immediately practicable scheme for the better government, organisation and development of the University to which effect may be given by way of a Statutory Commission, and we are convinced that with the lapse of time and material change of circumstances some of the main recommendations of the Haldane Report have lost their force, and that the ground for attempting to impose such an entirely new constitution on the University as the Report proposed no longer exists."

"A practical scheme of reform and reorganisation must, in our opinion, be evolutionary rather than revolutionary, and build as far as possible on existing foundations, which are characteristic peculiar to the University of London. Since we were established, the University has developed steadily during the past twenty-five years, even though hampered by serious constitutional defects. For the removal of these defects we are obliged to recommend some fundamental changes."

Having thus indicated the conservative interpretation which they had felt justified in placing upon their terms of reference, they set forth in less than fifty short pages the general outlines, not of an ideal scheme for inscription on a *tabula rasa*, but of the amendments to the existing constitution which they considered at once necessary and adequate; and it is upon this slight fifteen-penny pamphlet, characterised and sympathetically, sufficiently reasoned in form and singularly attractive in style, that the Commissioners of 1926 have based their Statutes which are to come into force immediately upon their approval by His Majesty in Council.

Before considering these in detail I think I may profitably summarise and explain those paragraphs of the Departmental Committee's Report which set forth the principles that determine and dominate their general scheme, those of all respectively with reference to External Students, to the Incorporated Colleges, and to the School of Dental and Medical Sciences, and to the other Schools and Faculties.

No feature of the work of the University has been so important as that of the School of Dental and Medical Sciences, which has been the subject of

such intense and at times acrimonious controversy as the conferment of degrees upon all persons who pass the necessary examinations, in whatever locality and by whatever methods prepared for their successive tests. As I mentioned in my article which appeared in THE LANCET on September 24th, 1927, all degrees had since 1858 been so conferrable except in Medicine and Surgery. The arguments on each side need not be repeated here, but the Haldane Commission were strongly out of sympathy with the whole system, and, though they did not in so many words advocate its abandonment, they expressed with some vehemence their conviction that "there can be no doubt that in the broader national interests the sooner the demand for External degrees can be reduced to a point at which the degrees themselves can be abolished without hardship the better it will be for our schools and our teachers." At an early stage of their deliberations the Departmental Committee made public their unanimous opinion that External examinations "have in the past served, and will in the future serve, a useful purpose," and in their Report they bore testimony to the "growing sense of harmony in the University" which it would be gratuitous to disturb. They further declared that they did not propose to interfere with the system, inaugurated in 1900, by which the advisory administration of the External Department generally was placed in the hands of a Committee consisting mainly of the representatives on the Senate of the graduates in Convocation, which body had "in the past been regarded as the protector of the interests" of the External Student. Such a system was confessedly illogical (especially as the personnel of Convocation was from the nature of the case steadily losing its original predominantly External complexion), but in practice it did not work inconveniently; and in view of the friendlier relations then existing between the two sides they recommended its continuance—not only in consideration of its historical basis but also as a matter of general policy.—This matter of External degrees is, of course, of less interest to medical graduates and undergraduates than to those in any other Faculty; but I mention it here, not only because the general principle involved affects the organic structure of the University at large, but specially out of regard to that small and regularly decreasing number of candidates who have been and are being prepared for their examinations for London degrees at approved Schools of Medicine in the provinces and throughout the Empire.

(ii) The constitution of 1900 provided the University with a number of specially privileged "Schools" and a further number of diverse and heterogeneous Institutions as the administrative constituents of its Internal side. In 1907 University College was by an agreed Act "incorporated" in the University—that is, transferred bodily to the complete control of the Senate—and in 1910 King's College (excluding its Theological Department) followed suit, the immediate supervision of each being entrusted to a specially constituted Committee acting on the spot.⁵ The Haldane Commission, recognising the difficulty of the situation thus developed from the point of view of the Schools which had not so surrendered their independence, were in favour of a comprehensive and complete extension of the policy of incorporation, which had indisputably led to certain economies both of cost and of manpower by the consolidation of administrative and teaching functions of others. In the first instance they recommended that at once in the past century those of the existing Medical Schools which had submitted to the statutory incorporation in the University should be placed under the Departmental Committee for Dental and Medical Sciences. This was the basis of the proposal to incorporate the Schools of Dental and Medical Sciences, which has been the subject of

anticipated; the policy was not generally approved throughout the University; and, apart from questions of sentiment, its extension would be attended by serious practical difficulties. "As regards the Medical Schools," they reported, "there was not only the difficulty of separating them from their parent hospitals so as to enable them to undergo a form of incorporation, there was also the difficulty of selecting from the twelve general Medical Schools the three which could and should qualify for incorporation." They further laid stress on the point that, whereas the recommendations of the Haldane Commission as regards this Faculty were integrally concerned with the proposed institution of Medical and Surgical Units under the control of University Professors, this policy had since that date been actually carried out (as I shewed in my article of October 1st, 1927) by the natural growth of the University and the development of intimate relations between the Senate and the governing bodies of the several Medical Schools. For these and other reasons, further incorporations were not to be encouraged, still less compulsorily imposed on unwilling Schools. But, for the creation of a closer bond between the University and its constituent administrative units as such, these units should be directly represented on the Senate; further, a new statutory Committee should be established, under the designation "the Collegiate Council," which should advise the Senate on "institutional and inter-institutional matters" in the same way as the Academic Council at present advise that body on the nature and scope of the teaching to be given, subjects of study, curricula, and examinations. With a view to the elimination of an embarrassing heterogeneity of style and the maintenance of a high standard throughout the category of Schools, the Senate should be empowered to weed out the smaller and weaker among them, and to exercise a paramount control in such matters as public appeals for support, the acceptance of benefactions, negotiations for grants, the appointment and titles of principal teachers, and the terms of governing instruments.

(iii) Closely allied to this problem of administrative symmetry was that of financial co-ordination. The University itself, the Committee pointed out, had no resources adequate for the control, or even the guidance, of a comprehensive policy, and this although the total income for the latest year under review of the twenty-two Schools (including for this purpose the two Incorporated Colleges) in receipt of grants from the Treasury amounted to nearly £1,000,000, of which £377,695 represented recurrent grants from the University Grants Committee and £78,366 aid from the London County Council.⁶ This was an intolerable situation. "It is," they declared, "fundamentally inconsistent with the idea of a self-governing university that it should not have sufficient financial resources and authority to initiate and pursue a policy of well-balanced development and to prevent wasteful duplication and competition. . . . The University would not be worthy of the name if it were not in its corporate capacity active in initiating, fostering and directing development on a considered and far-seeing plan." This view they supported by impressive quotations from recent Reports of the University Grants Committee⁷ and the London County Council,⁸ the two largest channels of public financial support; and it has been generally recognised that they have made out an indisputable case for entrusting to the University itself, as statutorily responsible for the execution of a coherent policy throughout its appointed sphere, the various grants

that are now or may in the future be made available for this purpose.

(iv) To enable the University to perform effectively these additional duties, a structural alteration was proposed with regard to the exercise of the ultimate authority. Since 1900 the Senate has been its "supreme Governing and Executive Body," charged with "the entire management of and superintendence over" its "affairs, concerns and property," subject only to the provisions of the Statutes of that date. This was now to be changed—not, however, as the Haldane Commission had recommended, by the establishment of a "Court," of "about 200" members, entrusted with ceremonial and legislative functions; this the Committee regarded as a redundant complication. Their design was less elaborate and more directly practical. The Senate, reduced from 56 members to 49, was to remain responsible for educational policy and detail; but a new creation, the "Council," of 16 members, only nine of whom should be members of the Senate, was to be set up "to determine the allocation of funds for the execution of university policy and generally to exercise control over finance." The exact constitution of these bodies and the details of their respective powers and functions, as set out in the Statutes based on the Departmental Committee's Report, will be dealt with later. But the considerations which led the Committee to advocate this partition of the supreme authority between two bodies, each paramount within its own sphere, may most properly be set forth here. "It is not in our view," they reported, "a desirable or practical proposition to charge with the ultimate control of university finance a large body consisting of directly appointed representatives of particular interests. Such a body may well be suitable to formulate policy having financial implications, but in our view there can be no doubt that the deliberations of the Senate would be more effective and its conclusions more judicial if the final decision on financial issues rested with a smaller body on which it was adequately represented, and on which those whom we may call the 'University members' were in a majority." The Council was therefore to consist of nine members of the Senate as against seven non-members—four appointed by the Crown, two by the County Council, and (for it may be taken for granted that he would fall within this category) one expert to be co-opted at their discretion by the other fifteen members.

It was this proposal upon which criticism pounced most promptly and intensively when the Report of the Committee was published in March, 1926; it is the only point upon which the members were not unanimous. Mr. H. B. Lees-Smith, agreeing with all the other recommendations of his colleagues, expressed himself, in a Minority Report, irreconcilably opposed to the transfer of the last word in finance to an independent correlative authority including so large a proportion of persons who were not members of the Senate. He felt it to be essential, if the University was to be "self-governing" in the full sense of the term, that the body charged with the control of its finance should consist entirely of members of the ultimate authority in educational matters—"no University," he urged, "can benefit by the government of men, however eminent, who cannot give the time to enter into its life and understand its problems." He had no objection to the title of "Finance Council" (which would emphasise its proper correlation with the Academic, External, and Collegiate Councils), or to the constitution proposed for it by his colleagues; but it should be, like the present Finance Committee, a subordinate body, in the main advisory, reporting to the Senate on the financial bearings of recommendations submitted on educational or administrative grounds by other Committees. The Senate would thus retain its existing supremacy in finance as in all other departments of the activities of the University.

The Departmental Committee made no direct reference to Mr. Lees-Smith's dissidence on this point,

⁶ The totals are at the present time considerably in excess of these figures.

⁷ "The University of London," say this Committee, "is in no real sense master in its own house. . . . This is an undignified position for the great University of the capital city of the Empire."

⁸ "The Council are convinced that their total grant in aid of University education in London should be given as a 'block grant' to the Senate," but state that, "while the constitution and powers of the Senate remain as at present," they cannot adopt this arrangement.

but they justified their novel scheme in a series of weighty paragraphs in which his objections are met, as are also those which have since been raised by various parties on the grounds that there would be a grave risk of constant delay, friction, and possible deadlock, and that in any case the dignity of the Senate would suffer grievously by such abridgment of their powers. Accepting fully the contention that "in the last resource finance determines policy," they pointed out that they had given the Senate "preponderance" on the Council, and that "substantial agreement on the Senate in matters of policy would thus profoundly influence the views and decisions" of that body. Moreover, the Council, with its smaller and more homogeneous membership, would be far better fitted than the Senate, the members of which were appointed on other grounds by a variety of constituencies and must necessarily be controlled by more formal procedure, to effect "the practical, expeditious and final adjustment of means to ends." To which deliberate vindication by themselves of their own action may be added the reflection that, in actual fact, there is no great administrative authority in the country—whether the governing body of a School or Hospital, a Borough Corporation or County Council, or even His Majesty's Ministry itself—which would lightly ignore or over-rule the considered protest of its financial advisers, even though these exercised a directly subordinate function confined to advisory representations. And on the point of prestige it should be borne in mind that the six or seven non-members of the Senate would, from the nature and conditions of their appointment, be no unsympathetic intruders thrust upon the University from outside, but one and all keenly interested in its prosperity and progress, though the very qualities to which they owed their seats might have rendered it impossible for them to accept a full share in its administration.

The remaining paragraphs of the Departmental Committee's Report deal with the nature of the offices of Vice-Chancellor and Principal, the constitution of the Senate and its several Standing Committees, the question of delegation and sub-delegation of powers, the removal of tiresome restrictions in procedure, the composition and functions of the Faculties and Boards of Studies, the area within which the University should operate, and the organisation of student activities. No vital or markedly controversial principles being involved in their recommendations upon any of these topics, it will be sufficient to summarise them as finally embodied in the new Statutes, with such explanations as may indicate to what extent and with what object, as shown in the Committee's Report, they modify or extend the Statutes at the present moment in force.

The Act of Parliament that followed upon the Government's approval of the Committee's Report received the Royal Assent on December 15th, 1926. By this Act eight Commissioners were appointed, with Mr. Justice Tomlin as Chairman, "to make Statutes for the University . . . in general accordance with the recommendations contained in the Report of the (Departmental) Committee, subject to any modifications which may appear to them to be expedient. . . ." They were specifically forbidden to make any Statute disturbing the accomplished incorporation of University College or King's College in the University, or actually to incorporate in the University any existing College, School, or other institution, any such action being reserved for future

agreement between the parties concerned. They were further directed, before definitely making any Statute, to facilitate by all suitable means the submission of representations by the Senate or other competent parties in the University or by other bodies or persons directly affected thereby.

The new Statutes were signed and sealed on July 23rd, and these it will be my business to summarise in a concluding article.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Private Practitioners and the Public Medical Services.

THE rapidly ripening problem of the relation between the private practitioner and public clinics of every kind is now receiving serious attention, and the new reforms in concentration of the public medical services give an admirable opportunity for investigating the relations of the private practitioner (insurance and other) to the available institutions for diagnosis and treatment. Stark opposition from the profession will no longer serve any good object. The growth of institutional equipment for diagnosis alone proves that large sections of everyday medicine are beyond the clinical competence of the average practitioner. It is necessary only to mention the polygraph, the electrocardiograph, and the X ray apparatus. No practitioner can be properly required to provide those appliances for himself, and yet no practitioner educated in modern methods would wish to work entirely without them. It follows that every practitioner should have access to the finely equipped departments at the large hospitals.

The Aim of the Social Worker.

In a recent address Prof. E. P. Cathcart, F.R.S., now Regius Professor of Physiology in the University of Glasgow, spoke strongly of the need of men and women for an outlet for the creative artistic spirit which all possessed in some degree. The social worker, he believes, should concentrate not so much on alleviation of fatigue in workshops as on alleviating and curing the boredom of free time. By giving the mind of man something on which it could concentrate more would be done than by clearing slums. He would like the Workers Educational Association and similar bodies to give the workers material not only for the brain, but for the hands—material that would give them opportunities for creation.

Cruelty to Children.

The Royal Scottish Society for Prevention of Cruelty to Children, founded in 1884, is one of the most important and active societies in Scotland. Last year there were 7235 complaints in which its intervention was asked, and these covered 10,160 parents and 21,156 children. There were 72,599 visits of supervision and 15,509 visits of inquiry. This gives some idea of the work done all over Scotland by this admirable organisation. At the recent annual meeting Lady (Leslie) Mackenzie, commenting on the difficulty of raising funds, suggested that, in the Edinburgh district alone, a farthing rate would raise all that was wanted, instead of the nominal sum of £12 contributed by parish councils. After expressing her shame that such a society should be necessary in the twentieth century, she pointed out that among the causes of ill-treatment were drink, bad housing accommodation, immorality, laziness, and unemployment. It was questionable, she suggested, whether the society was getting to the root of the problem. Sometimes those responsible for the ill-treatment of children required the attention of a mental doctor, and if something could be done for mentally deficient women she felt sure that the number of cases of fiendish ill-treatment would be reduced. The work of the society was one of the best bits of social reconstruction being performed, and she felt that the money should come in

* The other Commissioners were Sir Ambrose Selby-Bigge, Bart., Q.C., Sir Joseph Stamp, Sir George Perry, Mr. A. D. Brown, Mr. J. H. G. Macdonald, Mr. P. S. Phillips (formerly Secretary of the Scottish Education Department), Mr. J. H. G. Macdonald, and Mr. J. H. G. Macdonald. With regard to the latter three, it should be noted that Mr. J. H. G. Macdonald is a member of the University of London and is also a member of the University of Glasgow. Mr. J. H. G. Macdonald is also a member of the University of London and is also a member of the University of Glasgow. Mr. J. H. G. Macdonald is also a member of the University of London and is also a member of the University of Glasgow.

with a little less exertion on the part of a certain few people.

A primary defect in the Act, which was (somewhat prematurely, it appears) hailed as the Children's Charter, is that under it there is no single authority responsible for administration. For an Act that consolidates some 40 difficult criminal statutes a strong executive authority is demanded. This defect was pointed out years ago and a new inquiry into the working of the Act was suggested; but in the great flux of reforming events since the war this little item has excited no attention. Possibly in the new reforms something may be done.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Proposed Extension of Compulsory Insurance.

CLUB practice under the Workmen's Insurance Act is the principal source of income for the great majority of medical men in Germany. There is but little chance of private practice, owing to the decline of the former middle classes, affecting nearly everyone except certain employers of labour, the higher Government officials, and members of the liberal professions. So far well-paid employees have been exempt from compulsory insurance whilst workmen have been compulsorily insured according to the amount of their wages. The Act of 1911 limited compulsory insurance to those with an income of M.2500, this figure having since been raised to M.3600. Now, however, the Government intend to make insurance compulsory for all employees whose salary does not exceed M.6000 (£300) a year, and even for some classes of small tradesmen. The proposal is favoured by the sick-clubs, but has caused great alarm in the medical profession. Much has already been suffered by the recent extension of insurance to the families of insured persons, and it is feared that the new Bill will take away what is left of private practice, so that medical men will be more and more dependent on the clubs. Resolutions of protest have been passed by various medical bodies, based on various objections. The united Medical Chambers of Germany have petitioned against the Bill on the ground that there are private insurance institutions in which well-paid employees can insure themselves without any contributory payment by their employers. To well-paid employees the high contribution to the public insurance is disproportionate to the benefits received, which are the same for every class of the insured, whether the amount they pay is large or small. Under the new scheme, says the resolution, the medical profession would lose its independency; individual treatment under the club regulations would be replaced by schematic treatment, whilst the satisfaction medical men are deriving from their work would be reduced and they would suffer still further distress. The Leipziger-Verband have passed a similar resolution in which they point out that a proportion of medical practitioners are not admitted to club practice either because they have not been long enough settled in their respective place of residence or for some other reason. Some of them having already created for themselves a fairly satisfactory private practice, the extension of compulsory insurance to persons hitherto outside the clubs would deprive many medical men of their practice without compensation, and so be unconstitutional. The medical faculties of several universities, notably those of Munich and Würzburg, have protested. They regard the extension of compulsory insurance to sufficiently paid employees and to certain categories of small tradesmen as a further step towards the socialisation of medicine, which is apparently the aim of the Government.

Misuse of Orthopædic Appliances.

Orthopædic appliances are sometimes given rather lavishly by municipal authorities to patients not belonging to sick-clubs who, in the opinion of the municipal medical officers, require them to recover their

working capacity. Prof. Rost, chief surgeon to the municipal hospital of Mannheim, by sending nurses to the homes of the patients has lately made an inquiry whether the appliances distributed were really in use. The result of the inquiry was rather astonishing. Of 45 supporting corsets only 19 were regularly employed, and the same proportion, 19 out of 45, was given for walking-splints. Of patients with an amputated arm only 20 per cent. were wearing their artificial arm. Of five plaster-of-Paris beds only one was used. The percentage was satisfactory only for orthopædic shoes, 46 out of 50 being regularly worn. This was attributed to the fact that the patients in this way could save the costs of ordinary shoes. Some of the people concerned declared to the nurses that they were wearing their appliances for some hours every day, but this was obviously untrue. The money spent by the municipality on these appliances is thus for the most part wasted.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are statistics for 1927 for four county boroughs:—

Name of county borough and estimated (R.-G.) population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Diarrhoea, &c., under 2 years.	Maternal mortality from childbirth.
Derby (136,400) ..	18.0	12.5	0.70	1.38	2.7	1.8	68/11	3.2	2.8
Walsall (102,000) ..	20.8	12.7	1.11	1.10	2.8	1.9	96/41	8.5	4.2
Warrington (78,680) ..	19.6	10.8	1.27	1.12	2.4	1.7	77/27	5.1	6.4
Smethwick (76,870) ..	17.0	11.9	0.90	1.19	2.8	1.9	78/25	9.9	3.0

The pre-school mortality-rates per 1000 births were: Derby, 43; Walsall, 50; Warrington, 36; and Smethwick, 53.

Derby.

Dr. A. E. Brindley reports an increase in the general death-rate largely due to influenza. The deaths attributed to influenza numbered 113, nearly as many as those attributed to bronchitis and pneumonia respectively, which is quite unusual. There were 135 notifications of small-pox with no deaths. Dr. Brindley is convinced that the principal factor, in keeping alive the disease in the town and its reintroduction from outside districts, is the failure to elicit full information as to contacts. He would like legislation to make the giving of such information compulsory. As in many other districts new cases of syphilis show a decline and new cases of gonorrhœa an increase at the clinics. The number of scarlet fever cases admitted to the isolation hospital was 162 with no deaths. Treatment with antitoxin was adopted in the latter part of the year "with highly satisfactory results." There were 205 cases of diphtheria admitted with 7 deaths—a low case-fatality of 3.4 per cent. Since early in 1926 new nurses have been immunised against diphtheria and there have been no cases among the nursing staff. Early in 1927 two nurses developed scarlet fever, since which time scarlet immunisation has been adopted, successfully up to the present.

Of 32 samples of untreated milk three were found to be tuberculous and as a result one infected cow from a town byre was slaughtered. The other two samples were of "outside" milk.

Walsall.

Dr. James A. M. Clark says: "The housing question does not appear to be much nearer a solution as many bad cases of overcrowding are being constantly met with." A special effort was made during the year to secure the renovation of 250 of the worst houses. The work proceeded slowly and a number of the owners would have preferred Closing Orders. Many of the houses dealt with were occupied by more than one family without any conveniences for such dual or triple occupation. "The crying need in our present housing situation," says Dr. Clark, "is the provision of a self-contained dwelling at such a rent as will suit the income of the poorer classes, and, until some such provision is made, overcrowding and indecent occupation of rooms, leading to ill-health and immorality, will persist."

There were 344 notifications of diphtheria and 39 deaths, a case-mortality of 11.33 per cent. For three years immunisation facilities have been offered at the welfare centres with little response. Greater success was obtained in 1927 by a campaign in the schools with the co-operation of the teachers. During the last six weeks of the year 797 children and 52 adults in six schools were Schick-tested and the reactors immunised. Mr. Percival Mills, who conducts the orthopaedic clinic, points out the great advantage of the continuous treatment and supervision now available for the crippled children of Walsall, as compared with the past, when these children could only obtain their treatment by repeated journeys to Birmingham. During the year 184 cases were treated at the clinic.

Warrington.

Dr. G. W. N. Joseph reports that the housing problem has been somewhat relieved by the 348 municipal and 473 private enterprise houses built during the year. There are still 226 applicants living in overcrowded conditions. The Bewsey Estate of the corporation will provide 40 acres for housing and 27 acres for playing fields and recreation grounds. The municipal houses include 40 wooden huts with two bedrooms, living room, scullery, larder, w.c., &c. The larger huts are let at 9s. 5d. weekly, including rates, and the smaller at 7s. 5d. The lowest inclusive rentals among the remainder of the 600 municipal houses are A2 houses at 11s. 6d. weekly. In those houses which were relieved by the committee's selection of tenants during the year, the average number of occupants was 4.2 persons per bedroom.

An outbreak of small-pox (35 cases) originated in the poor-law hospital in December and continued in January, 1928. The type was mild and caused no deaths, but one man of 70 years died from intercurrent heart disease.

An orthopaedic scheme, conducted by Mr. Harman Taylor, of Liverpool, came into operation in June, 1927, and dealt with 20 boys and 26 girls of the pre-school age.

Smethwick.

Dr. Hugh Paul says the outstanding feature of the year was a disastrous outbreak of influenza, chiefly in the first quarter, which increased the general death-rate, the infant mortality, and the respiratory death-rate for the year. The housing problem is still acute and "a large number of families are living under most deplorable conditions." The houses built are only sufficient to provide for the increase of the population. There are 550 houses in need of reconstruction or demolition. The tenants of these slum houses would not, as a rule, be able or willing to pay the rents of better houses far removed from their work.

Dr. Paul thinks that antenatal work is showing its effect on the maternal and neonatal mortalities, and it is estimated that 30 per cent. of the pregnant women attended the antenatal clinic during 1927.

Toxoid antitoxin has been made available free of charge to medical practitioners for the prophylaxis of diphtheria, but little use is being made of this facility.

At the end of July there were five cases of dysentery distributed in a tenement house, occupied by several

families. A water-tank showed the presence of intestinal organisms and had been used for drinking purposes. A carrier, who had contracted this type of dysentery in the east, was living in the house.

MENTAL HOSPITAL REPORTS.

The *City of Portsmouth Mental Hospital at Milton* had 918 patients in residence at the end of 1927. The recovery-rate for the year was 29.9 per cent. and the death-rate 7.83 per cent. Of 75 deaths, 20 were due to general paralysis, 12 to kidney disease, and 7 to senile decay. There was no enteric or dysentery during the year, and only 7 cases of tuberculosis. Weekly cinema entertainments were much appreciated, and community singing has been started by means of broadcasting selected records through a gramophone attachment. The wireless has not yet ousted the hospital orchestra from its place in dances and entertainments. The out-patient clinic is doing good work; 171 new patients were seen in 1927, bringing the total to 872. The pathological laboratory has been re-equipped and a pathological assistant has been appointed. The work is steadily increasing. A new villa has been built, but further extension will be necessary. The visiting dentist has done a good deal of work. Parole is granted to 27 patients outside and to 110 inside the estate, and 50 patients were allowed out on trial before discharge. Two male and three female wards are administered on the "open door" principle. Thirty-seven men and 26 women nurses are certificated or registered; there is difficulty in getting suitable women probationers.

The *South Yorkshire Mental Hospital at Wadsley, Sheffield*, housed 1849 patients at the end of 1927, and additional accommodation, which had become very necessary, was obtained by opening a new hospital for boys and a new one for adult men, and by increasing the beds in the women's residence. The recovery-rate for the year was 39.9 per cent. and the death-rate 9.9 per cent. Autopsies were held on 95 per cent. of those who died. There were five cases of enteric fever during the year and one of dysentery, while 25 patients suffered from tuberculosis. There was also some erysipelas, influenza, and chicken-pox. Twenty-six cases were certified as suffering from the after-effects of epidemic encephalitis. The visiting physician remarks on the difficulty of detecting tuberculosis in insane patients and welcomes the provision of an X ray apparatus, which is also to be accompanied by an ultra-violet light installation. The visiting surgeon did a number of operations. The work of the visiting dentist is increasing, and much has to be left undone for want of time. Many male patients are usefully employed on the estate and on the farm, which last year gave excellent returns. Some of the women are busying themselves with the poultry and others work in the laundry and sewing rooms and about the houses. Thirty patients are allowed full parole, and 21 are free within the estate. 190 have been granted leave of absence for a few days, and a canteen for the sale (by token) of small luxuries is much appreciated. General paralysis is being treated by induced malaria. Of 114 cases who have been treated, 17 are well and employed outside the hospital, 9 are well but unemployed, 21 are improved, and 21 died. One sufferer from epidemic encephalitis improved after malarial inoculation, and the method is therefore being tested for these cases. In addition to routine work the pathologist has carried out several lines of research. An additional solarium, continuous bath and more open air verandahs are in course of construction. During the year six attendants and eight nurses passed the final examination of the *Medico-Psychological Association*, one nurse obtaining honours. A quiet "study room" has been provided for nurses and attendants. Two senior nurses fully trained in surgical and medical as well as in mental work have been appointed.

MENTAL DEFECTIVES.

The twenty-ninth report of the *Incorporated Lancashire and Cheshire Society for the Permanent Care of the Feeble-Minded* records a successful year of work, marred only by the impossibility of keeping pace with the demands for beds. A new house for 50 youths was opened last year, but the vacancies so formed could have been filled three times over. No more girls and women can be admitted, and the need continues urgent. To those who feel that the 371 beds at Sandlebridge are but a drop in the bucket, the secretary points out that if the 200 adult patients had been left uncared for there might by now have been 600 instead of 200, for the feeble-minded reproduce themselves more rapidly than any other class of the community. The inmates are happy and work steadily at various handicrafts. An unfortunate outbreak of scarlet fever caused many difficulties and kept out new patients for a time. An ophthalmic surgeon now pays quarterly visits. An urgent appeal is made for funds for this excellent work.

POOR-LAW REFORM.

THE GOVERNMENT'S PROPOSALS.

THE following account of the First Part of the new Local Government Bill is based on an explanatory memorandum¹ on the Bill's provisions.

1. Part I. of the Bill gives effect to the proposal to transfer the responsibility for poor-law administration to counties and county boroughs, as a necessary accompaniment of the scheme of rating reform. Clause 1 accordingly transfers, as from April 1st, 1930, the functions of boards of guardians to the councils of counties and county boroughs comprising the unions for which the boards of guardians act. If a union overlaps two or more counties or county boroughs, it will be divided among them. Clause 3 requires each council within a specified time after the passing of the Act to submit for the Minister's approval a scheme of the administrative arrangements to be made for discharging its new functions.

2. The poor-law will thus be transferred to authorities which already provide services, including institutions for medical treatment and other purposes, which overlap similar provision made by boards of guardians for persons who are destitute. Clause 4 accordingly gives power to the council to deal with destitute as well as other persons by means of the services which they provide under the special Acts mentioned in the clause. It is left to the council to determine whether they will avail themselves of this power, subject always to the maintenance of their legal obligations in regard to the relief of destitution. (The Lunacy Acts are excluded.) Other parts of the same clause permit the county council to make arrangements for cases appropriate for attention under the Education Act or the Maternity and Child Welfare Act, 1918, to be dealt with by those councils of county districts (non-county boroughs or urban or rural districts) which are separate education or maternity and child welfare authorities.

Public Assistance Committees.

3. Other classes of case (or, if the council do not elect to avail themselves of the power given by Clause 4, all cases) which require public assistance for the relief of destitution will be dealt with under the poor-law. Clause 5 accordingly requires the council to provide in its scheme for the establishment of a poor-law committee, called in the Bill the Public Assistance Committee, which may be either a new or an existing committee and may be assisted, if desired, by the inclusion of a minority of members not members of the council, among whom women must be included. All business relating to the transferred functions, except raising a rate or borrowing money, will stand referred to this committee. It may also have executive functions delegated to it, so that it can

give decisions without having to wait for confirmation by the council.

4. As members of a county council will not be able personally to deal with applications for poor-law relief from all over the county Clause 6 (1) (a) and (b) provides for division of the county into areas of one or more county districts in each of which a sub-committee of the Public Assistance Committee (to be called the Guardians Committee) of not more than 24 nor less than 12 members is to be set up, consisting of (1) members of the councils of the county districts in the area, nominated by the councils; (2) the locally elected members of the county council; and (3) members up to one-third of the total (among whom could be included aldermen of the county council) appointed by the county council.

5. It is not, however, intended that these committees shall be responsible for the provision of institutional treatment or, except as explained below, for the management of institutions. One object of the proposals in the Bill is to secure that existing institutions shall be used and developed to the best advantage. This involves the setting apart of particular institutions in the county to serve particular classes of inmates or particular purposes, for some of which a highly qualified staff and highly specialised apparatus may be found to be required. The organisation of the institutional service on these lines can only be undertaken, it is suggested, by a body viewing the needs of the county as a whole. But it will still be for the guardians committees by arrangement to send applicants for relief to the institution provided to meet their special needs and they will, if requested by the public assistance committee, be enabled to visit, report on, or manage institutions. Clause 6 (1) (c) accordingly enacts that provision is to be made in the county scheme for placing on the guardians committee the duty to

- (1) Consider and examine applications for relief;
- (2) Determine the nature and amount of the relief to be given;
- (3) Determine what part of the cost of relief shall be recovered from the recipient or from those liable for his maintenance;
- (4) Inspect, report on, or manage a poor-law institution in their area, if requested to do so by the public assistance committee.

The guardians committees will exercise the above functions subject to such restrictions or conditions as the county council may impose. The appointment and dismissal of officers will, moreover, remain in the hands of the county council.

6. To minimise the possible risk of loss of touch or absence of understanding between the guardians committees and the central public assistance committee Clause 6 (2) provides that a guardians committee shall be entitled to send a representative to participate in (but not to vote at) meetings of the public assistance committee when business relating to its area is to be transacted.

7. It has been shown in para. 5 that the prescribed organisation reserves to the county council the control of all services requiring the provision of institutions, in order to ensure that the institutions may be used to the best advantage. The position in county boroughs is the same. It will, however, be necessary for the councils of counties and county boroughs to make provision, as local authorities and boards of guardians now have wide power to do, for certain classes of case which are of regular occurrence, but relatively few in number. It is suggested that the most economical way of making this provision may be a combination of two or more councils for the purpose; thus it has been found convenient to make provision in one central institution in London for the radiological treatment of certain varieties of cancer. Experience is stated to have shown that the most effective control of vagrancy can be secured by the co-operation of authorities covering a wide area.

Clause 2 (1) and (2) accordingly gives power to councils to move the Minister to make an Order for their combination, and to the Minister, after making himself acquainted with the views of the local authorities and ratepayers concerned,

¹ Ministry of Health: Local Government Bill, 1928. Cmd. 3220. H.M. Stationery Office. 1928. 6d.

by Order to require two or more councils to combine for any purpose connected with their new functions under the Act, where such combination would tend to diminish expense or would otherwise be of public or local advantage. Sub-clauses (3) and (4) make provision for the administrative machinery necessary where combination takes place, and subclause (6) provides that any Order made by the Minister must be laid before Parliament and is subject to annulment on an address to His Majesty by either House of Parliament.

8. In order that the knowledge and experience of local conditions, which have been acquired by local authorities, shall be available in the final settlement as well as in the actual operation of the scheme, Clause 7 (1) provides that notice must be published by the county or county borough council in local newspapers that a scheme (see para. (1)) has been submitted to the Minister for approval, that a copy of it is open to inspection, and that representations on it may be made to the Minister within four weeks of the publication of the notice. Subclause (2) provides that the Minister must, before approving a scheme, consider any representations made to him by local authorities or other persons who appear to him to be interested. Subclause (3) provides that, if a council fails to submit a scheme, the Minister may himself make one, after consideration of any representations submitted to him by any local authorities.

9. In county boroughs also it may be necessary for the town council to seek the assistance of persons other than members of the council in the actual administration of their poor-law functions. Clause 6 (4) therefore gives the councils power to appoint subcommittees of the public assistance committee, in which a minority of persons not members of the council may be included. Subclause (4) (2) provides that the co-opted members shall include women, and that "regard shall be had to the desirability of including persons who are members of poor-law authorities immediately before the appointed day, and other persons of experience in the matters delegated or referred to the subcommittee."

Recovery of Costs.

10. The alterations in the arrangements for administering the poor-law which have been outlined in the foregoing paragraphs call for some modifications in the personal position of those who are affected, whether as administrators or beneficiaries.

(a) *Administrators.*—Clause 9 extends to membership of councils of counties and county boroughs and of the public assistance committee and its subcommittees the disqualification due to the receipt of poor-law relief, but puts an end to the present disqualification in the case of medical or surgical treatment.

(b) *Beneficiaries.*—Under the poor-law there is an obligation on the board of guardians where possible to recover the whole or part of the cost of relief from the recipient or from the persons liable to maintain him. Public health authorities, while they have a power to secure a recovery of this kind, are under no obligation to recover the cost of assistance given by them, e.g., under their tuberculosis and maternity and child welfare schemes—and the practice differs in different parts of the country.

Since it will be open to councils of counties and county boroughs in future to elect to give assistance in suitable cases either under the poor-law or under the special Acts, it might happen that repayment would be required from persons receiving assistance because they were destitute and had no open, but not from persons applying for it for their own recovery. Similar differences would arise between the public health authorities in different counties or county boroughs, according as the powers conferred on the councils by Clause 6 were or were not exercised.

The Memorandum points out that while the protection of the public health requires that a person suffering from an infectious disease should be given every inducement to seek hospital treatment, it is no less necessary that there should be no temptation to persons who can afford to pay the whole or part of the cost to look to public funds for free treatment and maintenance when they are ill. Nor is it desir-

able that the practice adopted in regard to the recovery of costs should vary in different localities. Clause 13 accordingly provides that it shall be the duty of the council to recover the whole or such part (if any) of the cost of maintenance as the patient or those liable for his support can reasonably pay, in all cases where persons receive *institutional treatment*, otherwise than for infectious disease (which includes tuberculosis and venereal disease). The present power of a local authority to recover the whole or part of the cost of assistance given under the special Acts (other than institutional treatment) remains unimpaired. Where treatment (or assistance) is given under the poor-law, the poor-law obligation to recover is left intact.

11. Certain amendments of, or additions to, the law relating to the functions of local authorities are also necessary. Among them Clause 11, Subclauses (1) and (2) confer on county councils the powers possessed by local sanitary authorities to provide hospitals for the sick, and extends the power so as to include ordinary maternity cases. Power is also conferred on councils to make subscriptions to voluntary hospitals. Subclause (4) removes the present restriction which prevents mental deficiency committees from treating poor-law mental defectives.

Subclauses (3) and (5) enable public health and mental deficiency committees of county or county borough councils to appoint subcommittees, consisting wholly or partly of members of the committees, and the first subclause gives the power (already existing in regard to the mental deficiency committee and other committees under the special Acts) to include in the public health committee, to the extent of one-third, persons not members of the council.

12. The following are the principal special provisions which apply to London. Clause 15 (a) and (b) leaves it to the London County Council to make arrangements for the local administration of poor relief by their administrative scheme, which will be subject to approval by the Minister. Subclause (d) provides that the London County Council shall absorb the Metropolitan Asylum Board, whilst Subclause (f) provides that the Common Council of the City and the councils of the metropolitan boroughs shall be responsible for vaccination and registration.

13. Arrangements are made for special cases in which boards of guardians under local Acts have powers which would not conveniently be fitted into a county scheme or hold property for charitable purposes. Clause 17 gives power to the Minister to postpone the transfer of poor-law functions from boards of guardians appointed by him under his special powers until April 1st, 1935.

The remaining parts of the Bill are briefly described in our Parliamentary columns.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED

NOV. 3RD, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 122 (last week, 148); scarlet fever, 3096; diphtheria, 1347; enteric fever, 28; pneumonia, 889; puerperal fever, 35; puerperal pyrexia, 107; cerebro-spinal fever, 1; acute poliomyelitis, 8; encephalitis lethargica, 20; dysentery, 9; ophthalmia neonatorum, 84. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylum Board on Nov. 6th-7th was as follows: Small-pox, under treatment 11, under observation 2; scarlet fever, 2715; diphtheria, 1935; enteric fever, 25; measles, 68; whooping-cough, 276; puerperal fever, 17 (plus 19 babies); encephalitis lethargica, 71; poliomyelitis, 2; "other diseases," 20. At St. Margaret's Hospital there were 16 babies with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 5 (3) from enteric fever, 11 (0) from measles, 6 (0) from scarlet fever, 10 (5) from whooping-cough, 42 (7) from diphtheria, 68 (21) from diarrhoea and enteritis

under two years, and 61 (13) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever outside London were reported from Salford and Sheffield. Three fatal cases of measles were reported from Walsall and 2 each from Coventry and Liverpool. Cardiff reported 6 deaths from diarrhoea, Manchester 4, and no other town more than 3.

The number of stillbirths registered during the week in the great towns was 271 (corresponding to a rate of 40 per 1000 births), including 39 in London.

Correspondence.

"Audi alteram partem."

GENERAL MEDICAL COUNCIL: ELECTION OF DIRECT REPRESENTATIVES.

To the Editor of THE LANCET.

SIR,—May I express my warmest thanks to all concerned for their generous support of my candidature in the recent election? The large number of votes recorded indicates an increased interest in the work of the Council, and will be to me an added stimulus to devote my best ability to the work, and to endeavour to justify the confidence placed in me.

I am, Sir, yours faithfully,

Wimborne, Nov. 6th, 1928. E. KAYE LE FLEMING.

To the Editor of THE LANCET.

SIR,—May I, through the medium of your columns, thank all those who voted for me in the recent election of two Direct Representatives as members of the General Medical Council. I shall endeavour to justify their confidence.—I am, Sir, yours faithfully,

Luton, Nov. 10th, 1928. JOHN W. BONE.

THE "RANGE OF UREA-CONCENTRATION" TEST.

To the Editor of THE LANCET.

SIR,—Would you allow me to correct a slight error in my letter in your last issue. In making my first comment on the urea-index 4.8 I really had in mind Dr. Hunt's general statement on the "urea-index" and this I omitted to quote: "This is of particular service in the recognition of the presence and degree of nitrogen retention." My remark, therefore, should have been that such low indices as 4.8 were not in keeping with the normal blood-ureas generally obtained in this particular form of kidney disease.

I am, Sir, yours faithfully,

Harley-street, W., Nov. 8th, 1928. E. G. B. CALVERT.

To the Editor of THE LANCET.

SIR,—Dr. Calvert has been kind enough to show me his further letter to you on this subject. To avoid any misconception I should also like to emphasise the point to which he refers and to make clear that the calculation of the urea-index—a matter which does clearly not affect the actual carrying out of the test—was not suggested to act as a guide to the condition of the blood-urea in the hydremic type of nephritis, but to repeat that it was in the cases I had grouped as "chronic interstitial nephritis" that it has been of value "as a useful index of nitrogen retention." It has the advantage of associating the three variants (maximum concentration, minimum concentration, and range of urea) under one figure, and showed itself to be of assistance when considering a number of cases, and in estimating to some extent the state of nitrogen retention in the cases of "contracted kidney" which were described.

Calvert's test has been in cases of "large white" kidney perhaps least reliable, and this applies with

especial force to any such formula as the urea-index. As Dr. Calvert rightly states, "urinary tests of function have a very limited value in acute or subacute kidney conditions where oedema or hydraemia is present." This is particularly to be regretted, since he insists that "it is preferable to base our diagnoses or classification on the results of function tests" and "to rely rather on ability than appearances." It was with the hope that a better insight into function might be obtained that I proposed extending the dilution part of Dr. Calvert's test over a longer period; though it is perhaps true that "prolonged and elaborate investigations with the water test may, unless great care is taken, lead to wrong conclusions," it is unfortunately also true that the shorter test as originally suggested by Dr. Calvert has, in the actual cases that were under consideration, sometimes itself led to wrong conclusions.

I am, Sir, yours faithfully,

St. Mary's Hospital, W., Nov. 12th.

T. C. HUNT.

ATYPICAL OR MILD ENTERIC.

To the Editor of THE LANCET.

SIR,—In your last issue (p. 972) Dr. Eustace Thorp reports seeing a large number of cases simulating typhoid fever, but with a negative Widal reaction. Several of these cases later showed a positive reaction, even long after convalescence. My object in writing is to report the seeing of a series of cases of differing disorders, prevalent for some weeks, and much more so in the last few days, all of which show as the most positive finding marked acetonaemia. Many of these cases showed a temperature up to 104° F., especially in children, gradually coming down one degree per day—if treated on anti-acidosis lines—finally reaching normal almost coincident with the alkalinising of the urine (generally about a week). These cases have been masquerading under such diagnosis as meningitis, pneumonia, appendicitis, typhoid, paratyphoid fever, or toxæmia of pregnancy; but they all show the same urinary findings and respond to the same line of treatment. The urine frequently shows organisms of the colon bacillus group, and I have assumed that these cases were due to some form of the bacillus which had become pathogenic—perhaps *B. faecalis alkaligenes*. Investigations are being made along these lines, as negative Widal reactions have been returned in what seemed a typical case of typhoid.

May it not be a case of the soil disturbance—i.e., liver and blood chemistry—being the more important factor in these cases, activating into pathogenicity any organisms which may be present in a particular field? The condition is on a par with the situation where one sees a run of suspicious diphtheritic throats in an institution, but where all are reported as negative—only streptococci or micrococci, &c., being found—until the last case, it may be, comes back with a positive report for diphtheria. In all such cases, I consider, it is more the question of the disturbed blood state activating all germs present in such people's throats. The clinical appearance may be similar in all.—I am, Sir, yours faithfully,

Darlington, Nov. 10th, 1928.

R. CHALMERS.

"THE FOUR PLAGUES OF EGYPT."

To the Editor of THE LANCET.

SIR,—In a leading article last week under this heading, wherein you refer to my presidential address to the Tropical Section of the Royal Society of Medicine, you make use of expressions which are not mine and with which I wish to dissociate myself. You write that Egypt is "physically rotten." This she is not, or the fellahen would not show, as they undoubtedly do, such a marvellous change in character, appearance, and physique once they have got rid of the bilharzia and ankylostomiasis. Certainly the fellah is bowed down physically and mentally by the weight of the handicap of his endemic diseases,

but this is no more discredit to him than illness is to one of a more fortunate race.

I spoke of the 11,000,000 fellahs, the most important numerically and the most unfortunate portion of the community, and the import of my remarks was that England can render them considerable aid by watching over their medical interests, so that the Egyptian nation may the sooner avail themselves of the benefits they will assuredly reap from the fine institutions which they have built up under British guidance. The question of diabetes is irrelevant. The Egyptians are a semitic race, and diabetes may be somewhat prevalent amongst the upper classes, but it has no effect on national character or outlook. Sexual perversion I know little about. I was 17 years in Egypt and the Sudan and came across insufficient evidence to warrant so wide a statement as you print.

I am, Sir, yours faithfully,

J. B. CHRISTOPHERSON.

Devon-hire-place, W., Nov. 11th, 1928.

BORNA DISEASE.

To the Editor of THE LANCET.

SIR,—In your review last week (p. 984) of the important report on Borna disease by Nicolau and Galloway, published by the Medical Research Council, it is stated—quoting the report—that the disease is still unknown in the British Isles. Might I be allowed to point out that, though rare, the disease does occur here. Some years ago I had the opportunity of examining part of the central nervous system of a pony which developed the disease in the Island of Skye. Details of this case were published with a photograph of the lesion in a recent communication (*Proc. Roy. Soc. Med.*, February, 1928), where it was pointed out that the lesion shows great similarity with that of acute poliomyelitis.

I am, Sir, yours faithfully,

JAMES MCINTOSH.

Bland-Sutton Institute of Pathology, Middlesex Hospital, London, W., Nov. 13th, 1928.

MATERNAL MORTALITY IN CHILDBIRTH.

To the Editor of THE LANCET.

SIR,—The Minister of Health, as you announced on p. 911, proposes to hold an inquiry into each maternal death in the country. This, as far as it goes, is a step in the right direction, although it is applied at the wrong time.

There are three causes for the maternal death-rate, and they may be stated as (1) marriage of unfit persons; (2) inadequate antenatal work; and (3) housing conditions and overcrowding.

It is of little use making exhaustive inquiries after the event. To prevent such an incidence as 1 per 1000, it will be necessary to attend to these three points: (1) For the first point, medical examination and a "fit" certificate should be compulsory for both parties to a marriage. (2) Every pregnant woman should be examined (at a clinic or otherwise) by a medical man, and measured, and advised. As to (3) better housing conditions should be a first consideration, when the appalling condition of childbirth, occurring in a room occupied by children, probably only divided from the unfortunate woman by a curtain, if at all, will cease to exist.

Until these elementary things are attended to, it will be useless to attempt to reduce mortality below 1 per 1000. I am, Sir, yours faithfully,

CHAS. H. H. H. H.

W. J. GIBBINS.

NOTTINGHAM OBSTETRIC HOSPITAL.—Last week the Board of Public Health, the foundation stone of the new obstetric Hospital for Nottinghamshire at Hockley Wood. The building, the site for which has been given to the Public Health, will cost £25,000.

Obituary.

SIR NESTOR TIRARD, M.D., F.R.C.P. LOND.

WE record with regret the sudden death on Nov. 9th of Sir Nestor Tirard, who will be remembered as a physician who contributed much to the exactitude of medical treatment. He was in his seventy-sixth year, and death was due to cerebral hemorrhage.

Nestor Isidore Charles Tirard was a singularly brilliant student. He took honours in zoology at the preliminary scientific examination; he took the gold medal in

physiology at the London intermediate, and again the gold medals in forensic and obstetric medicine at the London final in 1877. His teachers at King's College were proud of these successes, which were but the beginning of a career of great distinction, for Tirard became a really learned man. At this time he was senior scholar and associate of King's College. He acted as vice-president of the Medical Society, sub-

SIR NESTOR TIRARD.

dean and medical tutor to the College, and lecturer on physiology and comparative anatomy to the evening classes. At King's College Hospital he served as house physician and Sambrooke surgical registrar before being appointed (1885) assistant physician, and in due course (1892) full physician, retiring in 1919, when he was appointed consulting physician. During the greater part of this time he was also on the staff of the Evelina Hospital for Children and physician to the Church Missionary Society and to St. Luke's Hostel. The completeness and breadth of his learning assured his choice as professor of the principles and practice of medicine; but only those who engaged him in conversation came to realise the profundity of his medical knowledge. As a physician Tirard was a master of the art of examination and of the deductions which could be made upon its results. His *Text-Book of Medical Treatment, Diseases, and Symptoms* (1900) was designed to help the student with a manual in which treatment held first place, but the book was more than a therapeutic treatise, for it dealt broadly with preventive and remedial measures for morbid conditions, and being written in a pleasing and attractive way, with sound and reliable instructions, the students of the time had good reason to be grateful to the writer. Apart from this systematic work Tirard wrote mostly on clinical matters—Bright's disease, diabetes, antitoxin treatment—his meaning always being expressed in fluent English; lucidity of expression was indeed his aim, and he liked to admire it in the writings or speeches of others. No sacrifice of time or temper was too great to attain it. His laborious care in choice of words sometimes seemed excessive, but it was needed for the work he had to do. The accuracy of his drafting was utilised in the *Therapeutic Substances Act* and especially in relation to the Pharmacopoeia.

He was also an extremely good linguist and his help was for that reason in great demand at international conferences.

Tirard gave freely of his time and labour to the advancement of pharmacopœial knowledge and to the improvement of pharmacopœial organisation. He was appointed editor of the *Pharmacopœia* Committee of the General Medical Council in 1895 and he was secretary of that committee at the time of the publication of the B.P. 1898. In that year he was requested to act as reporter to the committee on advances in pharmacology and therapeutics bearing on the *Pharmacopœia* and he was responsible for the Indian and Colonial Addendum of 1900. In June, 1910, he took part in the Paris conference which discussed proposals for an international understanding on the subject of Methods and Standards of Analysis in relation to food and drugs. In the following year he was appointed one of the editors of a new *Pharmacopœia*, and on resigning his secretaryship of the *Pharmacopœia* Committee in 1915 on account of pressing war duties a resolution of the Council placed on record an appreciation of his 20 years' service.

He examined in medicine for the Royal College of Physicians of London over a period of 15 years or more; he was a councillor from 1908-10, and in 1914 he delivered the Bradshaw lecture in which he made some clinical contributions to the study of glycosuria. The graphic records which were the basis of this lecture, the result of close coöperation with the pathological department of King's College Hospital, were effective in showing the relative influence of dietetic and medicinal treatment, leaving no doubt as to the paramount importance of diet. The lecture contained also a notable contribution to the relation of glycosuria to gangrene. During the war Tirard was appointed Lieut.-Colonel commanding the 4th London General Hospital and received the honour of knighthood in 1916. From 1922-27 he was a member of the General Medical Council as a Crown nominee, acting as hon. secretary to the *Pharmacopœia* Committee and representing the Council at the International *Pharmacopœial* Conference in 1924. He was also a member of the advisory committee for the testing and marking of glassware used for scientific purposes.

In spite of all these claims upon his time Tirard kept familiar with contemporary work in medicine and its outlying sciences, and although he did not enter the arena of research his judgment and criticism upon it were sound and enlightening. "I have often discovered," writes one of his colleagues, "how valuable was his advice when I wished to elucidate a difficult point." In hospital practice his juniors found him willing to give advice when it was required, and he took endless trouble in so doing. One who knew him best writes that he "always found him extraordinarily wise." He was fond of children, who responded to his generous and warm-hearted nature. For pastimes he was devoted to sketching in water-colours, and on returning from holiday he would bring with him a large album which was a source of pleasure in retrospect. Part of his leisure he spent in fishing.

Sir Nestor Tirard married in 1885 Helen Mary, daughter of the Rev. R. S. Beloe, by whom he had one son and two daughters.

JOHN MACINTYRE, M.B., LL.D.,
F.R.F.P.S. GLASG., F.R.C.S. EDIN.

THE medical profession in the West of Scotland loses a prominent member by the death of Dr. John Macintyre on Oct. 29th. The son of Donald Macintyre, he was born at Glasgow and educated at the University there. After graduating in 1882 he gained post-graduate experience at Vienna and returned to Scotland to practise chiefly as a laryngologist. He was appointed assistant surgeon to the Glasgow Royal Infirmary, subsequently becoming surgeon for diseases of the throat and nose, and lectured on the same subject both at the University and at Anderson's College, where he was dean of the Medical Faculty.

Twice President of the British Laryngological, Rhinological, and Otological Society, he was a Fellow and corresponding member of several foreign associations in the same specialty, being for some years joint editor of the *British Journal of Rhinology, Otolaryngology, and Laryngology*. From an early stage of his career, however, he also took a keen interest in the development of radiology. Quick to realise the importance of X rays, he was one of the first in Glasgow to make use of them in his work, and he began a long series of contributions to the literature of medical electricity and physics as long ago as 1885. His investigations on X rays were demonstrated to the Royal Society of London towards the end of last century, and Macintyre won general recognition as a capable and ingenious experimenter. He was elected president of the Röntgen Society and received the Fellowship of the Royal Society of Edinburgh. In 1918 he became a Fellow of the Royal Faculty of Physicians and Surgeons, and two years later was made a Doctor of Laws by his University. He was a justice of the peace and in 1917 was appointed a deputy-lieutenant for the city.

An enthusiastic yachtsman, Dr. Macintyre held a Lieut.-Commander's commission in the Royal Naval Volunteer Reserve. He married the daughter of the late H. R. Hardie.

Dr. JOHN CASHIN, whose death occurred in London on Oct. 28th, was for 35 years in practice at Southsea. Born in 1856 at Clogheen in Co. Tipperary, the son of Michael Cashin, of Cooldevane House, he was educated at Mount Mellarey Abbey School, the College School, Waterford, and Queen's University, Dublin. Qualifying in 1880, he became resident medical officer at the Jervis-street Hospital, and later resident obstetric officer at the Rotunda Hospital. After post-graduate training in London and Berlin and two years' service in the Royal Navy, he took up gynæcological practice in London, obtaining the diploma of F.R.C.S. Irel. in 1890. He was appointed surgeon to out-patients at the South London Hospital and assistant physician to the Soho-square Hospital for Women, and published several books on gynæcological subjects. Eventually, however, he decided to leave London and take up general practice at Southsea. A few years ago he was joined in partnership there by Dr. Warren Meade. During the war Dr. Cashin was in medical charge of troops at Portsmouth Barracks and was made an officer of the Order of the British Empire for his services. He married a daughter of Thomas Were Fox, of Plymouth.

Dr. JAMES CROSSLE SCOTT, whose death has occurred in Ireland after several months' illness, was an Ulsterman by birth and studied medicine at the University of Dublin. He graduated in 1902, proceeded to the M.D. degree in the following year, and at once entered private practice at Merton Park, Wimbledon. From 1916 until the end of the war he served as medical officer in various hospital ships, but afterwards resumed his work at Merton, where he was joined last year by Dr. Taylor Harris. He was 54 years of age, and leaves a widow with three children.

BOLTON INFIRMARY EXTENSIONS.—A gift of £10,000 to the Bolton Infirmary by Miss Barnes, of Bolton, in memory of her brother, is the second donation of £10,000 to the infirmary within a few weeks, the other gift being raised out of the estate of the late Mr. Colin Cooper. The joint sums will be used to build the first of four new hospital blocks, each containing two wards. The four additional blocks are intended to give 160 additional beds, a new out-patient department, a new operating theatre, and other offices. A contract has also been placed for the building of a new nursing home at Newlands, Chorley-new-road, to cost £30,000, the gift of the Haslam family. An X ray and sun-ray treatment department, built and equipped at a cost of £6000, was opened on Nov. 8th by Mrs. Tom Jackson, who, with her husband, gave the money for its construction.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation on Nov. 9th the following degrees were conferred:—

M.B. and B.Chir.—H. H. Stewart, W. P. Purvis, and D. J. MacMyn.

M.B.—Hon. W. S. Maclay.

The Gedge Prize for original observations in physiology has been awarded to Mr. W. A. R. Rushton, Ph.D., of Pembroke College.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a meeting of the Council on Nov. 8th Sir Berkeley Moynihan, the President, in the chair, Richard Anderson Hickling, M.B. Camb., M.R.C.P. Lond., of the Westminster Hospital, was appointed the fourth Streatfeild scholar, the subject of his research being an investigation of the Living Cells of the Blood and of Effusion into Serous Cavities by Means of Sabini's Supravital Staining Technique in Clinical Cases. The Diploma of Fellow was conferred upon Roland Hodgson Boggan, of St. Thomas's Hospital, who has now complied with the by-laws of the College.

Diplomas of Member were conferred upon 157 candidates (139 men and 18 women) who have passed the requisite examinations and have complied with the by-laws of the College. The names of these candidates appeared in our issue of Nov. 3rd, in the list of licentiates of the Royal College of Physicians, with the exception that H. T. Flint (Westminster), Margaret C. Rosser (Birmingham), and H. Joomye (Middlesex) have previously received the diploma of M.R.C.S. and H. Bernstein (University College) will receive the L.R.C.P. diploma at a later date.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—Dr. R. A. Fleming, the President, took the chair at a quarterly meeting of the College on Nov. 6th, when Dr. W. T. Benson and Dr. R. H. H. Newton were introduced and took their seat as Fellows of the College. Dr. J. D. Stuart Cameron and Dr. A. N. S. Carmichael were elected to the Fellowship. Hill Pattison-Struthers Bursaries were awarded as follows: Anatomy and Physiology, Wai-Ming Tso; Clinical Medicine, Alan Mackenzie Fraser.

ROYAL SOCIETY OF ARTS.—On Wednesday, Dec. 12th, at 8 P.M., a lecture on Applications of Electricity to Medical Practice will be given by Mr. G. G. Blake, M.I.E.E., at the Royal Society of Arts, John-street, Adelphi, London, W.C. Sir Oliver Lodge, F.R.S., will preside.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—Three lectures, illustrated by lantern slides, on the History of Medicine will be delivered at the school by Dr. Charles Singer on Nov. 19th and 20th, and Dec. 3rd, at 4.15 P.M. The lectures will be on small-pox, plague, and diphtheria respectively, and are open to all medical students of the University of London.

BRITISH SCIENCE GUILD.—The Norman Lockyer lecture for 1928 will be given by Prof. J. Arthur Thomson, Regius Professor of Natural History in the University of Aberdeen, at 4.30 P.M. on Wednesday, Nov. 28th, in the Goldsmiths' Hall, Foster-lane, London, E.C. His subject will be the Culture Value of Natural History. A few tickets are still available and may be had from the Secretary of the Guild, 6, John-street, Adelphi, W.C. 2.

BRITISH SERBIAN UNITS.—The annual re-union dinner of the British Serbian Units Branch of the British Legion and of all friends of Serbia will be held at the Victoria Mansions Restaurant, Victoria-street, Westminster, on Saturday, Dec. 1st, at 7.15 P.M. The President, Dr. Alice Hutchison, in the chair. Tickets may be had from Mr. J. R. Chappell, the interim hon. secretary, 123, Queen's-road, W. 2.

CLINICAL SOCIETY OF BATH.—A meeting of this society was held on Nov. 2nd at the Royal United Hospital, with Mr. A. de V. Blathwyt in the chair. Mr. J. S. Lewis showed a case of elephantiasis of the leg of unknown origin, in which he had performed Kondeleon's operation with great success. The oedema had disappeared and the leg was almost normal in size. The patient had returned to his work as a labourer. Dr. R. G. Gordon exhibited a cinematograph film illustrative of some abnormal gaits in children, as exemplified by some of the patients at the Bath Orthopaedic Hospital. He stressed the point of the educability of many cases of cerebral diplegia which had hitherto been generally looked upon as a condition of imbecility. He cited several cases of children at the Orthopaedic Hospital, who in addition to being taught to feed themselves and to walk, could also read, write, sew, and typewrite.

UNIVERSITY OF GLASGOW.—On Nov. 10th the degree of Doctor of Medicine was conferred on James Baird.

UNIVERSITY OF ST. ANDREWS.—Dr. John McGibbon, formerly of the University of Witwatersrand, Johannesburg, was on Nov. 9th formally installed to the Chair of Midwifery and Gynaecology in the University, in succession to Prof. J. A. Kynoch.

UNIVERSITY OF LONDON MEDICAL GRADUATES' SOCIETY.—The first extra-metropolitan dinner of this society will be held at the Queen's Hotel, Birmingham, at 7.30 for 8 P.M., on Friday, Nov. 23rd, with the President, Sir StClair Thomson, in the chair. Any University of London medical graduates wishing to be present are asked to communicate with Prof. W. Billington, 58, Harborne-road, Edgbaston, Birmingham.

NEW HEALTH SOCIETY.—A festival dinner of this Society will be held at the Mayfair Hotel, Berkeley-street, London, W., at 7 for 7.30 P.M., on Thursday, Nov. 29th, with Sir Charles Wakefield in the chair.

NORTH-WESTERN TUBERCULOSIS SOCIETY.—Dr. S. Vere Pearson, physician to Mundesley Sanatorium, will read a paper on Pitfalls in the Diagnosis of Pulmonary Tuberculosis on Thursday, Nov. 22nd, at 3.15 P.M., at the Public Health Laboratory, York-place, Oxford-road, Manchester. The attendance of all medical practitioners is invited.

FOREIGN DECORATIONS.—The King has given to Major B. H. C. Lea-Wilson, K.A.M.C., P.M.O., Egyptian Army, authority to wear the Insignia of the Third Class of the Order of the Nile, conferred upon him by the King of Egypt; and to Mr. A. Copland, district surgeon, authority to wear the Insignia of the Third Class of the Order of the Brilliant Star of Zanzibar, conferred upon him by the Sultan of Zanzibar.

DUBLIN UNIVERSITY BIOLOGICAL ASSOCIATION.—The opening meeting of this Association was held last Saturday evening in Trinity College, Dublin, having been postponed from Oct. 27th on account of the death of Mr. L. L. Cassidy. The President, Dr. D. G. Madill, delivered an address on Some Aspects of Midwifery in Early Times and in the Middle Ages. The speakers were Prof. Munro Kerr (Glasgow), Prof. C. G. Lowry (Belfast), Prof. T. G. Moorhead (Dublin), and Mr. L. G. Gunn.

MITCHAM COTTAGE HOSPITAL.—Princess Mary last week opened the Wilson Cottage Hospital at Mitcham, in Surrey, which has been given with an endowment by Mr. and Mrs. Isaac H. Wilson at a cost of about £60,000. The accommodation comprises wards with ten beds each for men and women, a children's ward with six beds, and four private wards. Two cots are to be given by the Prudential Assurance Co.

PRESENTATIONS TO MEDICAL MEN.—In June last Prof. L. P. Gamgee retired from 35 years' service to Birmingham General Hospital as successively resident surgeon, honorary assistant-surgeon, and honorary surgeon, and accepted the position of honorary consultant surgeon. Last week his long service was commemorated by the presentation of an address from the board and the medical staff, while the Lord Mayor, as President of the hospital, was asked to accept a portrait of Prof. Gamgee to be hung in the board-room. In his speech Prof. Gamgee attributed the distinguished position of the institution to the fact that it forms part of a flourishing medical school.—Dr. John Hedley Marsh, J.P., medical officer of health for Macclesfield, has been presented by his fellow practitioners in Cheshire with a corner cupboard, a bookcase, and a chair. A panel of the bookcase is formed by an illuminated address which reads as follows: "Presented to Dr. John Hedley Marsh, J.P., by the members and constituents of the County Palatine of Chester Local Medical and Panel Committees in recognition of his spirited leadership and of a decade of genial and judicious conduct in the chair." A Japanese garden enclosed in an oval porcelain tray was also presented to Mrs. Marsh, and a complimentary luncheon followed the presentation ceremony, but Dr. Marsh was unable to receive in person the tributes of esteem from his colleagues owing to illness.—On Nov. 7th Dr. Arthur Maddock Jones, of Bala, North Wales, was presented with an inscribed gold cigarette case and a cheque for a substantial amount on behalf of the inhabitants of the Bala district, in appreciation of his services while at Bala as medical officer for the Bala and Penllyn Councils, and as secretary of the Bala Golf Club. Dr. Jones will take up practice in Llandudno.

PHYSIOLOGY AND NATIONAL EFFICIENCY.—A lecture on this subject was delivered at King's College, Strand, on Nov. 14th, by Prof. R. J. S. McDowall, Dr. Andrew Balfour being in the chair. Prof. McDowall explained how national efficiency depended on the efficiency of the individual—and that to be efficient a man should always be capable of doing his best in the minimum time and with the minimum waste of material. He described how accurate rationing was based entirely on experiments performed in physiological laboratories, performed in the first instance in the pursuit of pure science; and further, how physiological investigations had resulted in the discovery of remedies for scurvy, rickets, diabetes, and many other ills.

DONATIONS AND BEQUESTS.—Miss Sarah Sutton, Coventry, left £1000 to the Coventry and Warwickshire Hospital, and £100 to the Coventry District Nursing Association.—Mr. John Hart, Maida Vale, London, W., left £1000 to such charitable institutions or objects as the executors may determine, and £250 each to the London Hospital, the Metropolitan Hospital, and the Jews' Hospital and Orphan Asylum; £200 to the Jewish Home for Incurables, St. Dunstan's Hostel; and £150 each to the Evelina Hospital for Sick Children, and the Hospital for Epilepsy and Paralysis.—Mr. H. C. Sayer, of Sheffield left, among other bequests, £1000 to St. Dunstan's Hostel for Blinded Sailors and Soldiers, and £100 to the Sheffield Royal Infirmary.

ULSTER MEDICAL SOCIETY.—The second meeting of the session was held at Belfast on Nov. 8th, with the President (Prof. T. H. Milroy) in the chair. Dr. J. S. Campbell read a paper on the Coronary Circulation in Relation to Coronary Disease, based on his recent research into the anatomy and pathology of the coronary circulation, as seen by injection of barium into the vessels and their subsequent radiography (see THE LANCET, July 28th, p. 168). He dealt, first, with the variations in the normal arrangement of the arteries and their anastomoses, and the changes which are associated with age—i.e., diminished vascularity of the right side of the heart, greater tortuosity, and more complex anastomoses of vessels. He then showed that thrombosis was relatively common, and found only in vessels previously diseased; that thrombosis was, in certain cases, compensated by a generous anastomosis, and, in particular, that the cardiac neuromuscular tissue is protected by a specially rich blood supply. Dr. Campbell illustrated his remarks by a series of lantern slides of his injected hearts as seen by X rays, and demonstrated the normal and pathological coronary circulation. Dr. J. E. MacIlwaine, Dr. S. B. B. Campbell, Dr. R. Marshall, Mr. S. T. Irwin, and the President joined in the subsequent discussion, and in congratulating Dr. Campbell on his fruitful research.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
TUESDAY, Nov. 20th.—5.30 P.M., GENERAL MEETING OF FELLOWS. Ballot for election to the Fellowship. 8.30 P.M., PATHOLOGY. Papers: Norah H. Schuster; Bilateral Lung Carcinoma. G. M. Findlay: Ultraviolet Light and Cancer. T. Izod Bennett: The Relation between Oedema and Nephritis.
THURSDAY.—8.30 P.M., UROLOGY. Paper: Mr. D. M. Morison: Routes of Absorption in Hydronephrosis. Experimentation with Dyes in Total Ureteral Obstruction.
FRIDAY.—5 P.M., DISEASE IN CHILDREN. (Cases at 4.30 P.M.) Paper: Dr. H. M. M. Mackay: Nutritional Anaemia in Infancy: Some Observations on a Common Deficiency Disease. 8 P.M., EPIDEMIOLOGY. Paper: Dr. H. P. Newsholme: Individuality and Epidemic Disease.

ROYAL INSTITUTION, Albemarle-street, W.
THURSDAY, Nov. 22nd.—5.15 P.M., Dr. E. D. Adrian, F.R.S.: The Mechanism of the Nerves.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, Cavendish-Square, W.
THURSDAY, Nov. 22nd.—8.30 P.M., Dr. L. A. Weatherly: Juvenile Psychologic Delinquencies: their Origin and Treatment. To be followed by a discussion.

CHELSEA CLINICAL SOCIETY.

TUESDAY, Nov. 20th.—8.30 P.M. (at the Hotel Rembrandt, Thurlow-place, London, S.W.). Mr. N. D. Bellis (Messrs. Abdulla and Co., Ltd.), Dr. W. E. Dixon, F.R.S., and Dr. G. E. S. Ward, will open a discussion on Tobacco. The meeting will be preceded by dinner at 7.30 P.M.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, London, W.C.

WEDNESDAY, Nov. 21st.—8 P.M., Sir Gerald Bellhouse, Chief Inspector of Factories: Safety in Factories.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE, MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Nov. 19th, to SATURDAY, Nov. 24th.—**MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.** Lecture by Mr. L. C. Rivett: The Signs and Symptoms of the Common Disorders of the Menopause, on Mon., at 5 P.M.—**CHARING CROSS HOSPITAL, Charing Cross, W.C.** Tues., 11 A.M. Clinical Demonstration by Mr. Graham Brown in the Ear, Nose and Throat Department.—**CENTRAL LONDON OPHTHALMIC HOSPITAL, Judd-street, W.C.** Thurs., at 3.30 P.M., clinical demonstration by Mr. Cardell.—**ROYAL CHEST HOSPITAL, City-road, E.C.** Tues., at 4.30 P.M. Clinical lecture by Dr. Saxby Willis: Bronchiectasis.—**WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C.** Wed., demonstration by Dr. E. G. French on The Aetiology of Various Skin Diseases at 4 P.M. There are no fees for the above.—**ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E.** Special post-graduate course in medicine, surgery, and gynaecology.—**ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, Broad-street, Holborn, W.C.** Special Course.—**ST. PETER'S HOSPITAL, Henrietta-street, W.C.** Special Course in Urology.—**WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck-street, W.** Lecture-demonstrations, illustrated by cases from 5 P.M. Further information from the Secretary.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Nov. 19th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Simmonds: Surgical Out-patients.
TUESDAY.—11 A.M., Mr. Edecan: Venereal Diseases (demonstration). 2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose and Ear Department.
WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Ironside: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Department.
FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.
SATURDAY.—9 A.M., Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.
 Daily 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anaesthetic Course.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Nov. 19th.—2.30 to 5 P.M.: Medical, Surgical, and Gynecological Clinics. Operations.
TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.
WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.
THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.
FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

WEDNESDAY, Nov. 21st.—4 P.M., Prof. Sir Thomas Oliver: Lead Poisoning in Industries.

CHADWICK PUBLIC LECTURES.

WEDNESDAY, Nov. 21st.—5.15 P.M. (at the Medical Society of London, 11, Chandos-street, W.). Dr. E. P. Cumberbatch: Physiotherapy, with Special Reference to Medical Electricity.
THURSDAY.—8 P.M. The above lecture will be repeated at the Guildhall, Bath.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Nov. 22nd.—4 P.M., Dr. Gray: Tuberculosis of the Skin in Children.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Nov. 23rd.—4 P.M., Mr. Gill-Carey: Diagnosis of Sinusitis.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Nov. 20th.—3.15 P.M. (at the Royal Chest Hospital). Dr. E. Maxwell: Heart Failure and Rapid Digitalis Treatment.

ST. PAUL'S HOSPITAL POST-GRADUATE COURSE, Endell-street, W.C.

THURSDAY, Nov. 22nd.—4.30 P.M., Sir Thomas Carey-Evans: Stone in the Bladder, with Special Reference to Treatment by Litholapaxy.

UNIVERSITY COLLEGE, Gower-street, W.C.
MONDAY, Nov. 19th.—5 P.M., Prof. E. B. Verney: Urinary Section. (Last lecture.)

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.
TUESDAY, Nov. 20th.—5 P.M., Dr. J. A. Drake: Leprosy.
THURSDAY.—5 P.M., Dr. A. Whitfield: Tuberculosis Cutis (1).

GRESHAM COLLEGE, Basinghall-street, E.C.
TUESDAY, Nov. 20th.—6 P.M., Sir Robert Armstrong-Jones: Care of Mental Illness.
WEDNESDAY.—6 P.M., The Brain and Sense Organs.
THURSDAY.—6 P.M., The Old and New Psychology.
FRIDAY.—6 P.M., Sleep (Gresham Lectures on Physic).

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.
MONDAY, Nov. 19th.—4.15 P.M., Dr. Charles Singer: Small-pox. First of three lectures on the History of Medicine.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.
TUESDAY, Nov. 20th.—4.15 P.M., Dr. W. Fletcher Shaw: Post-menopausal Hemorrhage.
FRIDAY.—4.15 P.M., Dr. W. G. Thomson: Some Problems in Psychiatry.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.
FRIDAY, Nov. 23rd.—3.30 P.M., Mr. Nutt: Ophthalmic Signs and Symptoms in Certain General Medical Conditions.

Appointments.

BARRON, H. THOMPSON, M.D. Lond., M.R.C.P. Lond., has been appointed Honorary Physician to the Skin Department, Craydon General Hospital.

CRITCHLEY, M., M.D. Brist., M.R.C.P. Lond., Junior Neurologist to King's College Hospital.

LESTER-WILLIAMS, R., M.B., B.Chir. Camb., F.R.C.S. Eng., Surgeon, with Charge of Out-patients at the Seamen's Hospital, Greenwich.

MATTHEWSON, G. D., F.R.C.P. Edin., P.M.O. of the Scottish Widows' Fund and Life Assurance Society.

SETTLEWORTH, EDITH A., M.B., Ch.B. Leeds, Resident Medical Officer to Doncaster Poor-law Infirmary.

Certifying Surgeons under the Factory and Workshop Acts:
GILCHRIST, T. B., M.D. Glasg. (Langport, Somerset);
PHILLIPS, A. P., L.R.C.P. Lond., M.R.C.S. (Chaddesley Corbett, Worcester); and **SCOTT, S. N., L.R.C.P. Lond., M.R.C.S. (Plymstock, Devon).**

Vacancies.

For further information refer to the advertisement columns.

All Saints' Hospital for Genito-Urinary Diseases, 91, Finchley-road, N.W.—Hon. Anaesthetist.

Birmingham and Midland Homoeopathic Hospital, Easy-row.—H.S. £150.

Birmingham, Queen's Hospital.—Asst. Opth. Surg. £50.

Birmingham University.—Lecturer in Physiology. £400.

Bradford City.—Asst. School M.O. £800.

Bradford, Royal Infirmary.—Res. Surg. O. £250.

Burnley, Victoria Hospital.—H.P. At rate of £125.

Cairo, Faculty of Medicine, Dental School.—Prof. of Dental Surg. and Path. £E.1200.

Cambridge, Papworth Village Settlement.—H.S. At rate of £100.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100. Also Surg.

Cardiff, King Edward VII. Welsh National Memorial Association. Asst. Tuberc. P. £600. Also Third Asst. Res. M.O. to N. Wales Sanatorium, Llangwyfan. £200.

Carlisle, Cumberland Infirmary.—Pathologist and Bacteriologist.

Carlisle, Cumberland and Westmorland Mental Hospital, Garlands.—Asst. M.O. £350.

Charing Cross Hospital, W.C.—2nd Surg. Registrar. £150.

Chesler, Royal Infirmary.—Three H.S.'s. Each £120.

City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—Res. M.O. £250. Also H.P. At rate of £100.

Colchester, Essex County Hospital.—Asst. H.S. and Registrar. £120.

Dagenham Urban District Council.—Asst. M.O. for Maternity and Child Welfare. £600.

Dreadnought Hospital, Greenwich.—Asst. Pathologist to London School of Clin. Med. £350. Also Med. Supt. £300.

Durham, Richard Murray Hospital, Blackhill.—Res. M.O. £150.

Eastbourne, Princess Alice Memorial Hospital.—Jun. H.S. At rate of £100.

Eastern Dispensary, Leman-street, E.—Physician.

Elizabeth Garrett Anderson Hospital, Euston-road.—Clin. Assts. £120.

Evelina Hospital for Children, Southwark, S.E.—H.S. At rate of £120.

Hampstead Hospital for Children, 30, College-crescent, N.W.—Pathologist. £50.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—Hon. Opth. Surg.

Hezheri Rural District Council.—Asst. County M.O. &c. £500.

Hospital for Sick Children, Great Ormond-street, W.C.—H.P. and H.S. Each at rate of £100. Also Res. M.O. for Country Branch Hospital, Tadworth, Surrey. At rate of £250.

Hull, Royal Infirmary.—Second H.S. At rate of £150.

King's College Hospital, Denmark Hill, S.E.—Sister-Matron. **Kirkmoorside, Yorkshire, Children's Orthopaedic Hospital.**—H.S. £150.

London Clinic, Ranelagh-road, S.W.—Ward Supt. £150.

London Homoeopathic Hospital, Great Ormond-street, W.C.—Asst. Phys.

London Lock Hospital, 91, Dean-street, W.—H.S. At rate of £200.

Manchester Hospital for Consumption and Diseases of the Chest, &c.—Res. M.O. £200.

Manchester, Park Hospital, Darghulme.—Three Res. M.O.'s. One at rate of £150 and two at rate of £120.

Merion and Morden Parishes.—M.O., and Public Vaccinator. £165.

Miller General Hospital for South-East London, Greenwich-road, S.E.—H.P. and H.S. Each at rate of £125.

Poplar Hospital for Accidents.—Hon. Dental Surgeon.

Portsmouth, Lymington Hospital.—Res. Asst. M.O. £300.

Prince of Wales's General Hospital, Tottenham, N.—Hon. Anaesthetist. £20. Also Hon. Clin. Asst.

Reading, Royal Berkshire Hospital.—Hon. Physician.

Royal Free Hospital, Gray's Inn-road, W.C.—Res. H.S.'s and Res. H.P.'s. Each £150. Surg. Reg. £200. Gyn. Reg. and Med. Reg. Each £100. Also Obstet. Dist. Asst. £100.

Royal Waterloo Hospital for Children, &c., Waterloo-road, S.E.—Pathologist. £250.

St. Albans and Mid-Herts Hospital and Dispensary.—Res. H.S. £150.

St. Thomas's Hospital, S.E.—Surgical Registrar.

Sheffield, Jessop Hospital, Norton.—Res. M.O. £150.

Sheffield, Royal Hospital.—Asst. Pathologist. £500.

Sheffield, Royal Infirmary.—Asst. Pathologist, &c. £500.

Southampton, Free Eye Hospital.—Hon. Clin. Asst. and Refractionist.

Surrey County Council, Kingston-upon-Thames.—Asst. M.O. £300.

Swansea Hospital.—H.S. £150.

University of London, South Kensington, S.W.—Geoffrey Duveen Travelling Studentship in Oto-Rhino-Laryngology. £150.

Walsall, General Hospital.—H.S. At rate of £125.

West London Hospital, Hammersmith-road, W.—H.P., H.S. Also Aural and Opth H.S. Each at rate of £100.

The Chief Inspector of Factories announces the following vacant appointments for Certifying Factory Surgeons: **Hawley (Staffordshire), Dewsbury (Yorkshire), and Jedburgh (Roxburghshire).**

Births, Marriages, and Deaths.

BIRTHS.

BOWDEN.—On Nov. 8th, at Bryn Bella, Bettws-y-Coed, the wife of Dr. T. R. Bowden, of a daughter (stillborn).

RICHARDSON.—On Nov. 3rd, at Palmerston-place, Edinburgh, the wife of Major D. T. Richardson, M.C., R.A.M.C., of a daughter.

MARRIAGES.

DIXON—SEYMOUR.—On Nov. 6th, at St. Martin-in-the-Fields, Joseph Francis Dixon, M.A., M.D., Lieut.-Colonel, R.A.M.C. T.A. (retired), to Helen Scott, younger daughter of the late Charles Pennington Seymour and Mrs. Seymour, of Rushbrooke, Co. Cork.

FAGAN—BEAUCHAMP.—On Nov. 10th, at the Church of St. Peter and St. Paul, Great Missenden, Bucks, Richard Feltrim Fagan, M.B., B.S., D.P.H., of Gerrards Cross, Bucks, to Evelyn Frances Joyce, only daughter of the late Captain W. G. Beauchamp, R.I.M.

SELBY—HAILSTONE.—On Nov. 8th, at St. Stephen's, Cheltenham, Harold J. Selby, M.R.C.S., L.R.C.P., to Cara, daughter of the late Commander W. Hailstone, R.N., and Mrs. Hailstone, of Ridgeway, Cheltenham.

DEATHS.

DAVIES.—On Nov. 5th, Philip Lys Davies, M.C., M.B., D.P.H.

SMITH.—On Nov. 2nd, suddenly, at Cork, Major-General J. B. Smith, C.B., C.I.E., I.M.S. (retired), of Gordon-road, Ealing. Medical Adviser to the Secretary of State for India and President of the Medical Board, aged 63.

TIRARD.—On Nov. 10th, suddenly, at Harley-street, Sir Nestor Tirard, M.D., F.R.C.P., aged 75.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

DEBATE ON THE ADDRESS.

THE debate on the motion that an humble Address be presented to His Majesty thanking him for the gracious speech from the Throne was continued in the House of Commons on Thursday, Nov. 8th.

MR. CLYNES moved the following amendment:—

"But regret that, although your Majesty's advisers have had four years of office with a commanding majority in Parliament, general election pledges remain unfulfilled, the country is burdened with the problem of unemployment in a more acute form, in many mining areas appalling conditions prevail, the proposals outlined in the gracious speech are utterly inadequate to meet the existing industrial situation and ignore the need for
tions of labour, and, in particular, regret
pledge with respect to factory legislation
that it is the declared intention of your
Majesty's advisers not to honour it during this Parliament."

He said that perhaps the worst of the broken pledges standing to the account of the Government since they took office in 1924 related to factory legislation. That was a matter which must not be treated lightly, affecting as it did the lives and health of many millions of operatives in this country. It was some 25 years since there had been any general revision or treatment through any comprehensive Act of Parliament of factory life and conditions. The Prime Minister had informed the Leader of the Opposition that the reason why the Factory Bill found no place in the programme for this session was that there was no time. All the Prime Minister's supporters must have felt from the tone in which that statement was made that the Prime Minister himself knew that it was a most feeble and unconvincing reply, and carried no weight whatever in any quarter of the House. The Home Secretary at the beginning of the session of 1926 made this statement:—

"I desire with the full authority of the Prime Minister to state clearly and distinctly that the pledges to pass the Factories Bill during the course of the present Parliament are not only not to be waived, but are this night emphasised by me on Mr. Baldwin's behalf."

A little later, on March 26th, the Home Secretary said in the House:—

"The Factories Bill will be one of the principal measures of next year, and we will do our utmost to pass it into law. That is a categorical statement which I have been authorised to make."

The English language could not go further. But in spite of these expressed declarations and repeated assurances and reassurances they had now the statement from the Prime Minister that there was no time to do anything of the kind. The Prime Minister had denied that there was any pressure exerted to cause the Government to withhold their hand in respect of this particular Bill. If it were true that it was their own spontaneous act, done of their own free will, the case against them was all the greater. There surely was ground for some suspicion of pressure when they followed the terms in which Ministers had addressed themselves to this question. The Home Secretary, speaking on Oct. 28th, 1927, said:—

"The Bill will make balustrades and staircases in factories compulsory. Fancy balustrades being regarded as rank Socialism! It will make mechanical shuttles take the place of the present methods and conserve the health of women. Every week one man is killed in mills through being caught in overhead shafts. Is it rank Socialism to prevent that? If so, I would be ashamed of the Conservative party if they failed to prevent it."

He (Mr. Clynes) would like to know the measure of the Home Secretary's shame when at the end of this debate the division was to be taken on the question of this gross violation of repeated pledges. He was quite certain that if the Conservative conference at Yarmouth had been as enthusiastic in demanding the Factories Bill as it was in demand of the Ante-Trade Union Bill the Factories Bill would have been passed into law.

MR. CHURCHILL (Chancellor of the Exchequer) said that it must not be thought that the feelings of distress which the appalling conditions in parts of our coalfields had caused was confined to any one party. He repulsed the suggestion that there was any want of humanity in the British treatment of the unemployment problem. There was no country in all the world where direct taxation of the rich and wealthy in all its forms was carried so far. There was no country where so great a proportion of the national income was spent on the relief of sickness, old age, unemployment, destitution, widowhood, and orphans. He had taken some advice on this point, and although he admitted that the figures could not be taken as precise, yet he thought that it would be true

to say that man for man and woman for woman we in these islands provided two or three times as much—and it might be four and five times as much—as any other country in the world, including the most wealthy and also the most Socialistic country, for the care of the sick and the poor. When they examined the course of events which had occurred in their lifetime, surely they must feel that the problem of unemployment, grave and serious as it was, was of all others one which should not be used for ordinary party purposes; it was one which they should treat as a common problem which British men and women should try to face together. British industries were classified for the purpose of unemployment statistics into 100 groups, and in those groups there were now about 1,000,000 wholly unemployed persons. But of that number half were found in only nine groups, and it was upon those nine groups that more than half of the whole rating relief which the Government proposed to give to industry would be concentrated. In the remaining 91 industrial groups, considered as a whole unemployment had for the last two or three years remained relatively low; it had actually lessened in the last three or four years. The improvement in general industry, and especially in basic industries, was the first hope of providing new openings for displaced miners.

Mr. Clynes had referred at some length to the failure of the Government to fulfil pledges in regard to the Factories Bill. The Government proposed to appeal to the country at the first moment after their de-rating Bills had been passed and the necessary financial business had been settled. How, then, was there time for a Factories Bill as well as the de-rating Bills? The Government had had to choose between the de-rating measures, which were their main contribution to trade revival and the relief of unemployment, and this desirable factory legislation. Could anyone doubt that it would be wrong to delay a general election for the sake of the Factories Bill, or to give a Factories Bill at this time priority over de-rating legislation? When de-rating had brought its relief to industry the Factories Bill would follow naturally. On the whole, the conditions in the factories of this country were better than those which prevailed on the continent of Europe. But they could not say that British industries were in a more favourable position than the industries of the continent. With trade and unemployment as they were at present it was absolutely necessary that a measure of relief should precede and not follow additional regulations, however desirable.

The debate was adjourned.

Tuberculous ex-Service Men.

The debate was resumed on Monday, Nov. 12th.

MR. HAYES drew attention to the Government's policy in regard to tuberculous ex-Service men. He said that it might not be generally known that the treatment of these men, whose disability was accepted as due to war service, had been handed over by the Ministry of Pensions to the Ministry of Health. A case of a man, aged 50, in Liverpool, who was in receipt of 100 per cent. pension for tuberculosis, had come to his notice. The man was living in a slum with five other members of his family. On the advice of his panel doctor the man applied for sanatorium treatment, but he was informed by the local representative of the Ministry of Pensions that his case had been referred to the local authority, which in Liverpool was the Port Sanitary Hospitals Committee. After consideration that Committee decided that they could not admit the man to any of their sanatoria. He had therefore to return home to bed. What he (Mr. Hayes) was concerned about was the statement by the local authority that they could not admit this man to a sanatorium while there were other patients on the waiting list who have not yet had an opportunity of benefiting from sanatorium treatment. Further, the local authority stated that sanatorium accommodation on Merseyside was fully occupied, so that if this man was given a bed another patient would be deprived of it.

DR. DRUMMOND SHIELDS said that the unemployment problem had not been seriously tackled. Since the war we had spent nearly £400,000,000 just to keep people alive, and no more than alive. We had nothing to show for it, and we had subjected these people to a very serious ordeal and to great suffering and privation. After the war, the problem should have been tackled just like the war, and we ought to have had a general staff to deal with it. It was not sufficiently realised that the amount which was given in unemployment relief was not sufficient to maintain physical health in those to whom it was given. Undoubtedly, there was a very large amount of ill-health and malnutrition throughout the country. The Ministry of Health sometimes stated that there seemed to be evidence that people were not making claims for national health insurance who were not entitled to do so. He believed a very great deal of that was primarily due to unemployment, and that the physique and health of the people were being steadily undermined by it. That in itself, from the point of view of the physical

fitness of our nation, especially in view of the revelations of the war, was a subject which should appeal to all patriotic people. While he was in favour of emigration, he was very anxious that conditions in Canada and Australia should be such as would justify them in encouraging people to go there. A great deal of injustice had been done to the disabled ex-Service men. They had found it practically impossible to obtain work, and many of them, with their small pensions, had had a very miserable time. Their pensions ought to be brought up to the subsistence level.

Dr. VERNON DAVIES said that if the Labour Party, instead of going about making so many vain promises, would concentrate on the work to their hand, and see that the conditions of the workers abroad were brought closer to English standards, we should very quickly overcome one of the great causes of unemployment. Dr. Shiels had spoken about unemployment benefit, but he was criticising an Insurance Act and not a relief scheme. It was never suggested that the money paid under that Act would be sufficient to keep a healthy man or woman in good condition, but it was an insurance scheme, and those concerned were getting a good return for their contribution. Unemployment was a great problem and was causing great anxiety in the country. People generally had no conception of what people in Lancashire had been going through during the last seven years. Recently, in Lancashire, he was astonished to see how well-dressed the people were, but he was told that in more than one place they were saving money on their food. They were not spending half as much on food as in the good times. We could not afford that, and he suggested that if an opportunity occurred the Prime Minister or the President of the Board of Trade should offer his services to bring peace in the cotton industry.

Mr. RYAN DAVIES said that in some of the mining districts local authorities who had hitherto been able to provide meals for necessitous school-children were in dire financial straits. In a little district in his division called Aspall there was a population of 7000. Nearly all the pits were closed and some of the men had been unemployed for two, three, and even four years. The infantile mortality-rate, which was 85 per 1000 for Great Britain as a whole, was 128 per 1000 in that area. The Government ought really to study the terrible effect of unemployment on infantile mortality as well as on mortality generally. The figures relating to the payment of sickness and disablement benefits to the insured population of this country were an additional proof that our people were suffering much more severely than many Members of the Government would admit.

The Labour Party amendment was rejected by 321 votes to 151—majority against, 170.

LOCAL GOVERNMENT REFORM.

Mr. CHAMBERLAIN (Minister of Health) on Monday, Nov. 12th, presented in the House of Commons a Bill to amend the law relating to the administration of poor relief, registration of births, deaths, and marriages, highways, town planning, and local government; to grant complete or partial relief from rates in the case of the hereditaments to which the Rating and Valuation (Apportionment) Act, 1928, applies; to discontinue certain grants from the Exchequer, and provide other grants in lieu thereof.

Sir JOHN GILMOUR (Secretary of State for Scotland) presented a Bill to transfer to county councils and the town councils of certain burghs in Scotland functions of existing local authorities relating to poor relief, lunacy and mental deficiency, education, public health, and other matters; to amend the law relating to local government in Scotland; to grant relief from rates in the case of the lands and heritages in Scotland to which the Rating and Valuation (Apportionment) Act, 1928, applies; to discontinue grants from the Exchequer for certain purposes in Scotland, and to provide other grants in lieu thereof.

Both Bills were read a first time.

THE LOCAL GOVERNMENT BILL.*

Registration of Births, Deaths, and Marriages.

Part II. covers much the same ground as a Private Member's Bill of last session which passed the House of Commons but was not, through lack of time, proceeded with in the House of Lords. Clause 18 transfers to the councils of counties and county boroughs the functions of boards of guardians under the Registration Acts, but without, for the time being, disturbing the area of existing districts. Clause 19 (1) and (2) puts all new appointments on a salaried basis, and gives existing registration officers the right to become salaried. Subclause (3) gives the council the right to fix salaries and conditions of service, and provides that all fees shall be paid over by salaried officers

to the councils. Clause 20 (1) gives power to the Minister, by order, to increase the fees by not more than 50 per cent. Subclause (2) requires officers remaining on a fee-earning basis to hand over to the local authority that part of the total fees received by them which is due to any increase in the scale made under Subclause (1). It will not be possible to disturb the existing system or areas before the Census of 1931 is taken, because the local arrangements for the Census will be in an advanced stage of preparation by the spring of next year. Clause 21 requires the councils of counties and county boroughs before April 1st, 1932, to prepare a scheme, for the Minister's approval, of the local establishment and organisation of registration personnel, which will otherwise remain, so far as relates to the performance of their registration duties, under the control of the Registrar-General in order that the necessary uniformity of practice may be maintained throughout the country. Subclause (2) provides that the clerk to the county council, and the town clerk of the county borough council, shall be the officer responsible for supervising the local administration. Subclause (4) secures to interested officers the right to have any representations they may make considered by the Minister before a scheme is approved. Subclause (5) gives the Registrar-General power, after consultation with the council, to make a scheme for the approval of the Minister if the council fail to make one. By an Act passed in 1888 the salary of the Registrar-General was fixed at £1200. Clause 22 meets the present situation by providing that the salary of the Registrar-General shall be such as may be determined by the Minister of Health with the approval of the Treasury.

Inconvenience is often caused to members of the public by the necessity (unless they have since removed from the district) of attending to register births and deaths at the office of the registrar for the subdistrict in which the event took place. In many cases some other registrar is more easily accessible. Any modification of the existing practice in connexion with the registration of deaths and stillbirths is complicated by the need for medical and other certificates and certain unavoidable formalities. Clause 23 (1) permits births to be registered by means of a declaration to a prescribed registrar who is not the registrar of the subdistrict in which the birth occurred. Subclause (5) gives the Minister power to make or approve regulations extending this modification of the present procedure to the registration of deaths and stillbirths. In the application of this part of the Bill to London: Clause 24 provides that the functions of boards of guardians shall be transferred to the Common Council of the City of London and to the councils of metropolitan boroughs and not to the London County Council.

Town Planning.

Part III. of the Bill deals with roads and town planning. At present county councils have no powers of taking any formal part in the preparation and administration of town planning schemes—a state of affairs which, even apart from the present proposals, has been shown by experience to be unsatisfactory. Clause 33 empowers county councils by agreement to act jointly with other local authorities in preparing or adopting town planning schemes and to be represented on joint committees that already exist for the purpose. Clause 34 empowers the Minister, after holding a local inquiry, unless all the authorities concerned are in agreement, to constitute a joint town planning committee by Order. Clause 35 (1) provides that a county council may be made the responsible authority for carrying out appropriate duties, more particularly in connexion with roads, under a town planning scheme; and Subclause (2) that, where under a scheme approved before the appointed day, a rural district council are the responsible authority as regards any functions relating to roads, streets, or building lines, the county council shall, as from the appointed day, be the responsible authority as regards those functions. Provision is, however, made enabling the Minister, by Order, to except from the transfer such functions as he thinks fit, or to provide for the exercise by the rural district council, subject to such conditions as may be imposed, of any of the functions so transferred. Under the existing law, councils of boroughs and urban districts with a population of over 20,000 are required to submit town planning schemes to the Minister by Jan. 1st, 1929. It is considered that an extension of the period for the submission of town planning schemes is requisite, and Clause 37 extends the period to Jan. 1st, 1939.

Miscellaneous Local Government Provisions.

The Government, in Part IV. of the Bill, following the unanimous recommendations of the Royal Commission on Local Government, have framed a comprehensive scheme for the adjustment and reorganisation of areas, and have made provision for other improvements. Clause 39 requires every county council, as soon as may be after the passing of the Act, after conference with representatives of county districts, to make a review of all districts wholly or partially within

* An account of the first part of the Bill, dealing with the poor-law, is given on p. 1048.

the county, and before April 1st, 1932, submit to the Minister such proposals as they think desirable for alterations of boundaries, unions of districts, the conversion of rural districts into urban or vice versa, or the formation of new districts. Provision is made for full publicity to be given to these proposals and for representations to be made to the Minister by interested parties. Proposals may include alterations of the boundaries of non-county boroughs and agreed alterations of the boundaries of county boroughs. The Minister may either make or refuse to make an Order giving full or partial effect to the proposals after consultation with the district councils, but a local inquiry must be held before a decision is given if a local authority objects to a proposal. Orders so made are to be laid before Parliament. Power is also given to the Minister, after consultation with the local authorities, to make proposals himself if the county council have failed to do so. Clause 40 provides for the making of subsequent periodical review by county councils after an interval of not less than ten years after the first review, and of consequent Orders by the Minister. In case, however, of objection by a borough to any proposal affecting it, the Order will be provisional only until confirmed by Parliament. Clause 44 (1) provides that a rural district council may contribute as part of their general expenses towards the defrayment of "special expenses"—i.e., expenses for water, sewerage, &c., which would at present usually be levied on a parish or combination of parishes and not on the district as a whole. Clause 45 (1) empowers county councils to contribute towards expenditure incurred by a county district in connexion with sewerage or water-supply, and Subclause (2) provides that a district council may by agreement with the county council relinquish in favour of the latter any of its public health functions. Under Subclause (3), in case of default on the part of a county district to perform a public health function, the Minister is given power, after holding a local inquiry, by Order to transfer the function to the county council.

Under the Public Health Act, 1875, the Minister has power to combine two or more county districts for the purpose of appointing a single medical officer of health. This power is used to make the employment of whole-time officers possible. Another way of achieving this object is the appointment of an officer who is at the same time an assistant county medical officer. But on March 31st, 1927, out of 1686 county district councils, only 505 employed a medical officer of health who gave his whole time to public duties; the remaining 1181 employed private practitioners. For all classes of local authorities the proportion of whole-time appointments of medical officers has only advanced from about a quarter to something over a third in the last half century. The Royal Commission were impressed with the need for quicker progress, and Clause 46 provides that county councils shall, in consultation with their county districts, formulate arrangements, by combination of districts for the purpose or otherwise, to secure that every medical officer of health subsequently appointed for a district shall be debarred from private practice; in case of default the Minister may formulate the necessary arrangements himself. Provision is made for waiving in exceptional cases the condition that whole-time service shall be given. Clause 47 makes statutory the power which the Minister has hitherto exercised of regulating the standard of qualifications for medical officers of health and health visitors.

The Royal Commission recommended that the local authorities who administer the school medical service should be empowered to represent to the Minister that they should also administer maternity and child welfare work within the areas for which they are local education authorities, in order that there may be continuity in the supervision of the health of children before and after reaching school age. At present there are 159 maternity and child welfare authorities who are not school medical authorities, and 26 school medical authorities (outside London) who are not maternity and child welfare authorities. Clause 48 provides that where in any district any service under the Maternity and Child Welfare Act, 1918, is being carried on by a council which is not the local education authority for the district, the Minister may, on representations being made to him by the local education authority, withdraw his sanction to the arrangement and provide for the transfer of the maternity and child welfare service to the local education authority.

It is plainly desirable that notifications of births should be sent in every case to the local maternity and child welfare authority. At present the latter may obtain an Order from the Minister to secure this, but a number of authorities have neglected to make the necessary application. Clause 49 therefore empowers the Minister to make the necessary Order even if the council concerned have made no application for it.

The responsibility for supervising midwives at present rests, with a few exceptions, on the councils of counties and county boroughs. But those councils of county districts which have maternity and child welfare schemes and have

established antenatal clinics and maternity homes, are deeply interested in the supervision of midwives, and are desirous that the work of the midwives should be supervised by them and not by the county council. Clause 50 permits the council of a county district which is a maternity and child welfare authority and employs a medical officer of health who is not in private practice, to apply to the Minister for an Order transferring to them the supervision of midwives, if, in his opinion, the circumstances justify it. Under Subclause (2) an Order may be revoked by the Minister at any time.

At present both county councils and councils of county districts may provide hospitals for the treatment of infectious diseases, but in some parts of the country there is a serious deficiency of accommodation of this kind. Under Part I. of the Bill practically the whole of the public institutions in a county will pass into the control of the county council, and some of the existing institutions may be suitable for use as infectious diseases hospitals. As the provision of hospitals for infectious diseases is, and will remain, a function of the councils of county districts also, the county council should be able to foster co-operation between the authorities owning the hospitals and also to secure that adequate accommodation is available for this purpose. This provision will round off the power given to county councils under Part I. to secure the proper classification of institutional treatment with a view to the efficient use and development of the institutions. Clause 51 (1) lays upon every county council the obligation of making a survey of the hospital provision for infectious diseases throughout the county. Subclause (2): When the survey is complete, the council, in consultation if necessary with the council of any adjoining county borough, must prepare a scheme for providing adequate hospital accommodation for infectious diseases. Subclause (3): The scheme may provide for the joint use of institutions owned by individual authorities, and for the provision of additional accommodation by the county council. Subclause (4): Where the council of a county district fails to provide the accommodation required from them under the scheme the Minister may transfer the functions of the councils of the local authorities under the scheme to the county council, to be exercised by them at the cost of the local authority. Subclauses (5) and (6): Schemes will not be effective until approved by the Minister, and in case of default the Minister may himself make a scheme. The clause contains the usual provisions for securing consultation with the interested local authorities at all stages.

Clause 52 enables the Minister, on application from the London County Council or of any association or committee which is in his opinion representative of the metropolitan borough councils, to provide by Order, subject to certain conditions as to consultation, for the transfer to all the metropolitan borough councils of any functions exercisable by the London County Council (other than functions transferred to them under Part I. of the Bill) or for the exercise of any such functions by the metropolitan borough councils as agents for the London County Council. The clause is included as the result of representations on the subject from both the London County Council and the Metropolitan Boroughs Standing Joint Committee. An Order may extend to the Common Council of the City of London, if they consent.

Parts V. and VI. of the Bill deal with rating and valuation, and Exchequer grants and other financial provisions.

Property, Liabilities, and Officers.

Part VII. of the Bill deals with property, liability, and officers. Clause 93 with the sixth schedule provides for the transfer of the property and liabilities of boards of guardians to the counties and county boroughs which are their successors in function. Provision is made for adjustments in respect of property and liabilities, where the councils concerned so desire, if the present poor-law area is not wholly within a single county or county borough. Provision is also made for joint user of institutions. Clause 99 provides for the transfer of poor-law officers to the appropriate county or county borough council. Where they are attached to a particular institution or district, they will pass into the service of the council to which the institution or district is transferred. In other cases, if the union is divided up between one or more councils, the councils must agree, or failing agreement, the Minister must determine, to which council any officer is to be transferred. Clause 101 safeguards the existing tenure of transferred officers and provides that they shall receive not less remuneration while performing similar duties. Clause 102 safeguards the existing tenure of registration officers, and provides that for superannuation purposes they shall be deemed to be officers of the council to which the registration functions relating to their district or subdistrict are transferred under Part II. of the Bill. Clause 103 and Schedule VIII. provide for the payment of compensation to officers of authorities, from whom functions

are transferred, who thereby suffer any direct pecuniary loss. Clause 104, Subclause (1), provides that where the new authority have adopted the Local Government and other Officers' Superannuation Act of 1922, that Act shall (with necessary modifications) apply to transferred poor-law officers instead of the Act of 1896. Subclause (2) provides that, where the new authority have some other superannuation scheme in force themselves, they are to submit for the Minister's approval a scheme for substituting it for the provisions of the Act of 1896 in the case of transferred officers; when his approval has been given, the Act of 1896 shall cease to apply to them. Subclause (3) provides that where the new authority have at present no superannuation scheme, the Act of 1896 shall continue to apply to transferred poor-law officers. Subclause (4) deals with the case of poor-law officers who may after transfer become officers to whom the Asylum Officers Superannuation Act, 1909, applies. Subclause (5) provides that poor-law teachers who would, if they were serving in an elementary school, be covered by the Teachers' Superannuation Act, 1925, shall on transfer come under that Act instead of the Act of 1896.

General.

The transfer of poor-law functions and the abolition of existing poor-law areas is certain to give rise to difficulties in exceptional cases, which cannot be fully covered by the Bill. Clause 111 (1) gives power to the Minister to remove difficulties by Order. Under Subclause (2) every such Order is to be laid before Parliament, and by Subclause (3) of Clause 109 is to become void, if an Address against it is presented to His Majesty by either House within the next subsequent 21 days when that House has sat after the Order is laid. Under the proviso to Subclause (1) the power to make such Orders is to determine at the end of 1930.

PREVENTION OF MOTOR ACCIDENTS.

The Bill for the better regulation of road vehicles (which has been introduced into the House of Lords by Viscount Cecil of Chelwood) aims at diminishing the number of road accidents due to incompetent driving. The Bill requires all drivers to take out a licence after examination into their skill and physical fitness, and the Minister of Transport will be empowered to make general regulations to carry this provision into effect, and to make regulations requiring the production by the applicant for a licence of evidence, by a doctor's certificate or otherwise, that he is fit to drive a mechanically propelled vehicle. All motor vehicles will require to have a mechanical check on their speed, and third party insurance is to be made compulsory.

HOUSE OF COMMONS.

THURSDAY, NOV. 8TH.

Street Noises in Large Cities.

Mr. ERSKINE asked the Home Secretary whether he was taking steps to mitigate the nuisance of unnecessary street noises in London and other large cities; and, if so, the nature of his proposals.—Colonel W. ASHLEY (Minister of Transport) replied: I have convened a conference of all interests concerned to advise me what steps they consider could best be taken to mitigate unnecessary noise made by mechanically propelled vehicles. I hope to be in possession of their views at an early date.

Colonel WOODCOCK asked the Home Secretary if he was aware that the noise of motor-cycles without adequate silencers had in no way abated throughout the country; whether he could issue more stringent instructions to the police to deal with this great public nuisance; and, if the engines of motor-cycles did not conform to the police regulations respecting silencers, proceedings would be taken against the owners.—Sir W. JOYNSON-HICKS replied: I hope the action which has been taken has not been wholly without effect. The police will certainly continue to take proceedings and, I may add, the whole question of traffic noise is under consideration by a conference which has been convened by the Minister of Transport.

Colonel WOODCOCK: What special steps have been taken during the recess?

Sir W. JOYNSON-HICKS: We have prosecuted 10,000 cases from Jan. 1st of this year, so that the police really are carrying out their duties.

Mr. HARRIS: How far have the manufacturers been brought into conference?

Sir W. JOYNSON-HICKS: I am in constant conference with the manufacturers of motor-cycles, and am constantly pressing them to improve the silencers on their new motor-cycles.

Bogus Charitable Collections.

Colonel WOODCOCK asked the Home Secretary if his attention had been called to several recent instances of bogus charitable collections; and whether he proposed to take steps to carry into effect the recommendations of the

departmental committee which he set up, and establish some system of control over charity collections.—Sir W. JOYNSON-HICKS replied: The only recent case which has come to my notice is one in which a collector was convicted by a Scottish court. It would appear that the ordinary criminal law was adequate to deal with that case. As I have already stated, I am preparing a Bill to carry out the recommendations of the recent Inter-Departmental Committee.

Colonel WOODCOCK: Is the Home Secretary aware that these bogus collections and charities are very detrimental to the really good causes for which collections are genuine; and is he going to take steps to bring in legislation this session so that the recommendations of the Committee may be carried into effect?

Sir W. JOYNSON-HICKS: Generally speaking, the hon. Member has correctly stated the position. I am preparing a Bill, and the Prime Minister and the Parliamentary Secretary to the Treasury will say whether there is any possibility of it being carried this session.

Institutional Care of Mental Defectives.

Mr. ROBERT MORRISON asked the Minister of Health whether his attention had been called to the statement contained in the annual report of the Board of Control that there were 20,000 mental defectives for whom institutional care was required but was unobtainable; and what action he proposed to take.—Mr. CHAMBERLAIN replied: My attention has been called to this statement. Many local authorities are making further provision, and others are being urged to take action, in so far as is practicable in the present financial position. I anticipate that one of the results of the scheme of local government reform will be that local authorities will have spare accommodation available for this and other services of public health.

Institutional Poor-law Relief.

Sir WALTER DE FRECE asked the Minister of Health the average daily number of inmates in general poor-law institutions in England and Wales, the average weekly cost per inmate, and the total expenditure in connexion with those institutions for 1914 and each of the last ten years.—Mr. CHAMBERLAIN replied: The following statement contains such of the desired information as is available. It refers to general poor-law institutions in England and Wales administered under the Poor-law Institutions Order, 1913, including a few specialised institutions for which separate accounts are not kept.

Year ended March 31st.	Average daily number of inmates.	Average weekly cost per inmate of "in-maintenance."	Total expenditure in connexion with general poor-law institutions.
1914 } 1915 } ..	Particulars comparable with those for later years are not available.		£
1919..	110,607	10 5½	5,769,335
1920..	109,392	12 3½	7,251,563
1921..	127,927	14 2½	9,388,891
1922..	127,467	12 0½	Not available.
1923..	131,862	9 9½	7,889,037
1924..	132,967	9 6½	7,752,006
1925..	131,899	9 10½	8,140,699
1926..	134,418	9 11½	8,469,749
1927..	139,261	10 3½	8,783,769

* In-maintenance includes all the expenses incurred in and about the maintenance and treatment of persons in receipt of relief in general poor-law institutions—e.g., the cost of food, clothing, medicine, necessary expenses incurred in warming, cleansing, and lighting the institutions, and otherwise keeping them fit for daily use. It excludes the cost of buildings and repairs thereto, and furniture, and the salaries and other remuneration, rations, and superannuation allowances of officers and servants.

Coöperation Between Voluntary and Poor-law Hospitals.

Dr. LITTLE asked the Minister of Health what arrangements, if any, had been made to secure the coöperation of the voluntary hospitals and the hospitals now under poor-law administration, as contemplated by the Bill for the reorganisation of local government named in the King's speech as the principal measure of this session; if any estimate had been made of the probable cost of the provision at these municipal hospitals of medical and nursing services on the same scale as now obtained at the voluntary hospitals, where the medical services were mostly unpaid; and if he could furnish any information as to the measure of increase in the rates likely to follow upon the competition of the municipal hospitals with the voluntary hospitals in the event of no coöperation being achieved between these two classes of hospitals.—Mr. CHAMBERLAIN replied: The general problem alluded to by the hon. Member in the first part of the question has been actively discussed in many quarters for a very considerable

time. Definite local arrangements on the new basis cannot be entered into until the Local Government Bill has become law; and it is impossible in the meantime either to accept the assumptions which appear to underlie the remainder of the question or to base any estimates upon them.

Cost of Medical Inspection of Casuals.

Mr. CHARLES EDWARDS asked the Minister of Health whether he had received communications from boards of guardians requesting him to pay the cost of the inspection of casuals for the detection of small-pox from national funds; and if he would take steps to enable his department to do this.—Mr. CHAMBERLAIN replied: The answer to the first part of the question is in the affirmative. There are no funds at my disposal out of which such a payment could be made.

Medical Certification and Health Insurance.

Sir WALTER DE FRECE asked the Minister of Health whether he had any evidence that the increase in the expenditure on sickness and disablement benefit was in any way attributable to the administration of certain friendly societies and/or the laxity of doctors in the issuing of certificates; and, if so, what remedial action he was taking.—Mr. CHAMBERLAIN replied: I can best answer my hon. friend's question by saying that in endeavouring to ascertain how far the recent abnormal increase in expenditure on sickness and disablement benefits is attributable to causes which can and should be removed, I am receiving the full co-operation of approved societies of all types in inquiries for the purpose of securing that their administrative methods shall be fully efficient; and of the Insurance Acts Committee of the British Medical Association, who recently submitted to a conference of local medical and panel committees a number of detailed proposals, to which the conference agreed with certain amendments, for improving the procedure under which insurance practitioners at present carry out their duties with respect to medical certification.

Aged Persons and Health Insurance.

Mr. GROVES asked the Minister of Health whether he was aware of the dissatisfaction felt and expressed by insured persons who had contributed to the health insurance fund for many years and find themselves at the age of 70 precluded from further participation in the benefits of the fund; and whether he would take steps to enable them to continue to participate, especially in the case of those not eligible for old age pensions.—Mr. CHAMBERLAIN replied: I am not aware that there is any general dissatisfaction on the part of insured persons on the subject referred to by the hon. Member. An insured person ceases to be entitled to sickness or disablement benefit on attaining the age of 65, at which old age pensions now become payable, but notwithstanding the fact that thereafter he is under no liability to pay any further contributions either for health insurance or pensions, he remains entitled for the rest of his life to all the other benefits under the Health Insurance scheme—that is to say, to medical benefit, maternity benefit, and any additional benefits provided by his approved society in the form of treatment, such as dental, ophthalmic, or hospital benefit. I have no power to authorise the continued payment of sickness or disablement benefit after the age of 65.

National Insurance Drug Fund.

Dr. LITTLE asked the Minister of Health if, when making the agreement with the Retail Pharmacists Union relating to the National Insurance Drug Fund, described in the annual report of the Ministry of Health, 1927-28, the British Medical Association was consulted; if the approval of that agreement was obtained; and if, in view of the unanimous condemnation of the agreement as being against public policy recorded by two full sessions 1927 and 1928 of the annual conference of panel committees, he would rescind that agreement.—Mr. CHAMBERLAIN replied: Before the agreement with the Retail Pharmacists Union was actually concluded the Insurance Acts Committee of the British Medical Association were made acquainted with its terms by letter, and subsequently a conference took place at the Ministry when various criticisms and suggestions were fully discussed. The approval of the British Medical Association to the agreement as a whole was not invited, and has not therefore been obtained. At the conference of panel committees in 1927 a considerable difference of opinion was manifested although the resolution mentioned in the question was ultimately passed and reaffirmed without discussion in 1928. I am not prepared to rescind the agreement.

MONDAY, NOV. 12TH.

Medical Test for Metal Grinders.

Mr. WILLIAM THORNE asked the Home Secretary the number of metal grinders who had been discharged in consequence of failing to pass a medical test in accordance with the Statutory Rules and Orders, 1927, No. 380, in

respect to the metal-grinding industries (silicosis) scheme, and had not been able to qualify for workmen's compensation.—Sir W. JOYNSON-HICKS replied: No medical test for employment is imposed by this scheme. I understand that workmen employed by certain firms in these industries have been required by their employers for the purposes of insurance to pass a medical examination, and that some of them who failed to pass have been discharged, but I have no information as to the number affected. I may add that a workman employed at or after the commencement of the scheme has a right to claim compensation under the scheme for total disablement after he has left the employment, provided he has been employed in the dusty processes within the previous three years.

Compensation to Owners of House Properly.

Mr. BENNETT asked the Minister of Health if it was the intention of his department to introduce legislation in favour of the grant of reasonable compensation to owners of habitable house property which might be included in slum clearance schemes.—Mr. CHAMBERLAIN replied: It is the intention of the Government to introduce, at the earliest practicable moment, legislation dealing with slum areas, which will provide for an amendment in certain respects of Section 46 of the Housing Act, 1925.

Protection of Food from Contamination.

Mr. COUPER asked the Minister of Health what precautions were taken to protect food from contamination when displayed for sale; whether he was satisfied that such precautions were adequate; and what further legislation, if any, was contemplated.—Sir KINGSLEY WOOD replied: The Public Health (Meat) Regulations, and the Public Health Act, 1925, contain provisions for preventing risk of contamination of food offered for sale. No doubt the precautions taken by different traders in compliance with those requirements vary considerably, but on the information before him my right hon. friend does not think that there is any need for further legislation to extend the powers of control already possessed by local authorities.

Importation of Infected Sheep Carcasses.

Mr. WILLIAM THORNE asked the Minister of Health if he was aware that, in consequence of thousands of carcasses of mutton from Patagonian Chili being seized and condemned by the inspection authorities in the City of London on account of the disease known as caseous lymphadenitis, the authorities had placed an embargo on all wharves, stores, and markets within their area, and refused to pass for sale any sheep until the glands of the legs and shoulders had been incised and the carcass found immune; that the Port of London sanitary authority refused to adopt a similar procedure; whether any action was being taken to prevent the disease at the ports of Avonmouth, Cardiff, Liverpool, and Manchester; and what steps, if any, he proposed to take to prevent the flooding of the country with these infected sheep.—Sir KINGSLEY WOOD replied: Yes, Sir. I understand that it is the practice in the City of London to examine all sheep's carcasses for caseous lymphadenitis before they are distributed to retailers. The Port of London Sanitary Authority have recently decided to examine for this disease a percentage of the carcasses arriving at the docks, and to release the remainder to cold stores in the London area on condition that they are not removed therefrom without the permission of the local medical officer of health. My right hon. friend is making inquiries as to the practice at the ports of Avonmouth, Cardiff, Liverpool, and Manchester, and he hopes that it will be possible to arrange for uniform action to be taken at all ports for preventing the distribution of meat infected with this disease.

QUEEN ALEXANDRA'S HOSPITAL FOR OFFICERS.

Lord Melchett presided at the eighth annual reunion dinner held at the Hotel Cecil on Nov. 8th. He paid a tribute to the good work done at the hospital by all the members of the staff, and in particular by Mr. Herbert Paterson, who for the whole period of the war acted as honorary surgeon in charge. Lord Waring, who equipped and maintained an annexe to the hospital, was present at the dinner.

DEPUTATIONS ON NOISE.—Mr. Neville Chamberlain, Minister of Health, has consented to receive on Dec. 4th a deputation from the medical council of the People's League of Health on the effect of noise on the health of the community. The League last year laid before the Minister a petition signed by 10,000 persons in the streets. A deputation from the British Medical Association on the same subject will be received by Mr. Chamberlain at the same time, and will emphasise certain of the points which the Association has recently placed before him in a memorandum.

THE
Story
 OF
NICHOLAS CULPEPPER:
 ASTROLOGER-PHYSICIAN.

*Told in Responding to the Toast of "The Guests"
 at the Annual Dinner of the Royal Society
 of Medicine*

By RUDYARD KIPLING.

FELLOW-GUESTS,—I don't know how it is with you, but, when a medical man approaches me in the language of compliment, I am filled with an uneasy suspicion that somebody's tobacco is going to be rationed. That possibility, however, is behind us for this evening, so we can the better appreciate Colonel MacArthur's flattering diagnosis of our several virtues and merits. Some of us must have all of the symptoms indicated. I have one. I am a story-teller.

LORD DAWSON, members of the Royal Society of Medicine, gentlemen, and ladies, will you lend me your patience while I tell you a perfectly true story?

Nearly 300 years ago there was an astrologer-physician called Nicholas Culpepper, practising in Spitalfields. And it happened that a friend's maid-servant fell sick with what the local practitioner diagnosed as plague. Culpepper was called in as a second opinion. When he arrived the family were packing up the beds, preparatory to going away and leaving the girl to die. He took charge. There was no silly nonsense about looking for the characteristic plague tongue. He only asked at what hour the young woman had taken to her bed. That gave him, as I need not tell you, "the hour of the decumbiture." He then erected a horoscope, and "inquired of the face of the Heavens how the malady might prove." The face of the heavens indicated it was not plague but just small-pox, which our ancestors treated almost as lightly as we do. And small-pox it turned out to be. So the family came back with their bedding, and lived happily ever after; the girl recovered; and Culpepper said what he thought of his misguided fellow-practitioner. Among other things, he called him "a man of forlorn fortunes with sore eyes."

Preposterous as all this was, you must remember that Culpepper justified his practice by the theory that "this creation, though composed of contraries, is one united body, of which man is the epitome, and that he, therefore, who would understand the mystery of healing must look as high as the stars."

That was a distorted shadow of the ancient idea that the universe is one in ultimate essence—which essence is sustained and embraced and interpenetrated by a creative motion or inner heat—the pneuma of certain Greek physicians, who practised 500 years before St. Paul preached at Athens. It was a noble belief; but it did not prevent Dr. Culpepper from using a pharmacopoeia and therapeutics that would have made a West African witch doctor jealous. And when he came across anything that he did not understand, or that Aristotle had not provided for, he put it down to "influences" or "emanations"—same as you do a common cold.

But if he could return to earth to-day and see how things have progressed in the mystery of healing I fancy he would be quite at ease in your Zion. He believed in the transmutation of metals. He could be shown that in full blast at a Royal Society soirée—with emanations. He would find that the essential unity of creation is admitted as far forth as we have plumbed infinity; and that man, Culpepper's epitome of all, is in himself a universe of universes, each

universe ordered—negatively and positively, by sympathy and antipathy—on the same lines as hold the stars in their courses.

Consequently, he would not be astonished to see men snatch out of the air an influence—an inner heat or pneuma—of which they know no more than that it visibly warms, lights, and works for them, and, invisibly, transmits their speech and vision to one side of the world on the instant that they themselves speak or look from the other. And the news that unknown influences from out of the skies lash and tear through all matter everywhere at all times would be received by him with perfect calm.

Being an astrologer, he would, of course, go to Greenwich Observatory, to learn more about those influences. There he would be given monographs on terrestrial magnetism—its daily and seasonal tides the world over, magnetic storms, sunspots, auroras, and so forth, but all discussed without any relation to the severity or incidence of prevalent epidemics and diseases. From Greenwich he would certainly push on to the B.B.C., who would tell him that there are unknown heavenly influences which prevent millions of bold youths and blushing maidens from hearing the music they would dance to—influences which at times cause the spoken word to die out under the stars as the note of a rubbed finger-bowl dies when the hand is lifted.

Presently—for he was always stronger on theory than research—he would fetch up among the laboratories where, if he was as lucky as I was this summer, he would be shown marvellous films of infected tissue being subjected to the influence of an influence called radium. Then, I fancy, the fun would begin. Up to that point, he would find the main axiom which he had quoted three centuries before accepted, proven, and in use; the influence, the inner breath, the pneuma—not only exceeding all bounds of wonder and belief in its proper manifestations, but, under the name of electricity, piping and singing in the marketplace on a commercial basis.

So, as with his small-pox case, his first question after he had seen the films would be: "What was the aspect of the heavens at the time these phenomena occurred?" He would take it for granted that, with the whole universe alight to signal some tremendous secret to mankind, men would naturally look as high as the stars. And what answer would he get? When I asked a similar question of a man of science lately he said: "You'd better see a doctor." I told him that, with any luck, I expected to see ever so many of them before long. That expectation having been fulfilled to-night, I want to ask you some questions.

Isn't it likely that the multitude and significance of the revelations heaped upon us within the past few years have made men in self-defence specialise more and more narrowly? Haven't we been driven headlong to abandon our conceptions of life, motion, and matter? And isn't it human that in that upheaval men may have carried off each his own cherished prepossession and camped beside it—just as refugees do after an earthquake?

Is it then arguable that we may still mistake secondary causes for primary ones, and attribute to instant and visible agents of disease unconditioned activities which, in truth, depend on some breath drawn from the motion of the universe—of the entire universe, revolving as one body (or dynamo if you choose) through infinite but occupied space? The idea is wildly absurd? Quite true. But what does that matter if any fraction of any idea helps towards mastering even one combination in the great time-limits of Life and Death?

Suppose, then, at some future time when the bacteriologist and the physicist are for the moment at a standstill, wouldn't it be interesting if they took their problem to the astronomer, and—in modern scientific language, of course—put to him Nicholas Culpepper's curious question: "What was the aspect of the heavens when such-and-such phenomena were observed?"

palliative operations and almost always worth doing. I have had patients living useful lives three to five years after the operation. The least satisfactory is the operation of tracheotomy for laryngeal cancer, though it is hard to refuse it to a patient dying from asphyxia.

REPUTED CURES.

Finally, what are we to do when a patient who has heard of some reputed cancer cure wishes to try it and asks our sanction or even our coöperation? I do not think we should resent this attitude on the part of a patient; it is only human nature to follow a will-o'-the-wisp when all seems dark ahead; if the treatment proposed is not a secret remedy, and we can be sure that it will not do actual harm, I see no reason why we should not humour the patient and loyally do our best to help him; it will, at the

least, occupy his mind. If, however, the remedy or treatment proposed is harmful or a secret, as to the nature of which we are told nothing, I think we must refuse our sanction and, if the patient persists, refuse to take any responsibility and retire from the case.

Never tell a patient suffering from cancer or his friends that there is nothing to be done; so long as life lasts there is help to be given, and there are few forms of disease where the doctor can earn more gratitude than he can by his management of a case of inoperable cancer. In some cases where it is obvious that death would be the greatest mercy possible, it may be well for the practitioner to remember the words of the poet Clough:—

"Thou shalt not kill; but need'st not strive
Officiously to keep alive."

PARSON'S RESEARCH SCHOLAR, GUY'S HOSPITAL.

II.*

THE URINE.

A study of the urine has proved of very great interest and importance in allergic states, and it is no exaggeration to say that we can deduce from a given specimen taken from a person with allergic symptoms whether it was passed at the onset or during the paroxysm or in the period following it, and can also predict the urinary findings from the condition of the patient at a given time. There are two phenomena which we believe to be almost if not quite constant in persons with allergic symptoms at certain times during the periods of active manifestation—viz., the ether reaction discovered by one of us (G. H. O.), and the deposition of urates or uric acid in the urine on cooling. Before considering the urinary findings in detail it is advisable to summarise what we have found to occur in the cycle of events that takes place in all acute allergic states—e.g., an attack of asthma, urticaria, angeioneurotic

cedema, or migraine, and in the paroxysms of itching that occur periodically in prurigo and infantile eczema.

Cycle of Events in Allergic Conditions.

In the period just preceding and during the paroxysms we find:—

Blood.—1. The amino-acid content rises. 2. The uric acid and creatinine are apparently increased. 3. The chloride content of the whole blood falls.

Urine.—1. Free acidity rises. 2. Urates are often deposited when the urine cools. 3. Diminished water excretion, so that the specific gravity is usually high. 4. Retention of chlorides. 5. Ether reaction strongly positive. 6. Ammonia excretion rises and the ratio of free acid to ammonia-combined acid is altered. 7. Excretion of amino-acid, creatinine, and uric acid begins to rise.

In the period following the subsidence of the paroxysm we find:—

Blood.—1. The amino-acid content falls. 2. The uric acid and creatinine diminish. 3. The chloride content of the whole blood rises.

Urine.—1. The free acidity rapidly and progressively falls, and the urine tends to become neutral and finally alkaline, sometimes strongly so. 2. Increased excretion of water, so that the volume is raised and the specific gravity falls (post-paroxysmal diuresis). 3. The excretion of chlorides is increased. 4. The ether reaction diminishes and may entirely disappear. 5. The excretion of ammonia begins to fall, but lags, so to speak, behind the diminishing excretion of acid, so that the ratio of free acid to ammonia is still further altered. 6. Excretion of amino-acid, creatinine, and uric acid gradually falls.

For comparison the urinary findings in a case of true anaphylactic shock are submitted. (Table IV.)

CASE 10, a patient with ulcerative colitis, was one of simple anaphylactic shock which developed as the anti-dysenteric serum was actually being injected into a vein. The patient became collapsed and unconscious and there was incontinence of urine and faeces. Adrenalin was injected and consciousness rapidly returned.

The figures should be compared with those submitted in cases of allergic manifestations, such as asthma and urticaria,

* Part I. appeared last week.

* Per 100 c.cm. A.-c. A. = Ammonia-combined acid.

and reference should be made to the tabulated cycle of events that have been found to occur during and after the allergic paroxysm.

It will be noted that:—

1. The first specimen of urine collected after the shock deposited urates.

2. The first three specimens of urine contained albumin; albuminuria has been shown by Freeman to occur in hay-fever subjects after intravenous or subcutaneous injections of pollen extract, and by Rackemann, Longcope, and Peters in serum sickness.

3. The ether reaction was very strongly positive in all the urines of the first 12 hours following the shock and diminished gradually. (It had disappeared by the end of the third day.)

4. During the first 12 hours the free acidity rose very markedly; it then fell, but the ammonia excretion remained relatively high, thus disturbing the normal acid-ammonia ratio. The total free acidity for the first period of 12 hours was 281.8; that for the second period only 77.7.

5. The chloride excretion was low throughout, particularly on the evening of the second day. (It began to rise again on the evening of the third day.)

6. The creatinine excretion was high.

7. After an initial period of anuria the urinary excretion was very small, a highly acid, concentrated urine being passed; by the evening of the second day the post-paroxysmal diuresis had become established, and a large quantity of dilute urine of low acidity was excreted.

The Precipitation of Urates.

The precipitation of urates in the urine on cooling is a phenomenon that has not in our opinion received sufficient attention from clinicians. It is usually taught that such precipitation, when the urine cools, depends on (1) the concentration. (2) the acidity. As a matter of fact these are of relatively minor importance. We have seen a heavy deposit of urates in a urine with quite low free acidity and a specific gravity of 1012. As has been shown by Lichtwitz¹¹ and others, the solubility of uric acid and its salts depend upon the colloid state of the urine. The concentration is of subsidiary importance, for precipitation may occur with quite normal amounts, while abnormal amounts may remain in solution. Other conditions being the same, a sediment therefore occurs more readily in concentrated urine. The hydrogen-ion concentration is of significance merely in that precipitation only occurs in acid urines. *The dominant factor for the solubility is the state of the urine colloids* (Rosenbloom).

Since the precipitation of urates does not depend on the uric acid itself, such precipitation does not in any way indicate the "uric acid diathesis." Brugsch and Schittenhelm¹² have pointed out that whereas true gout is extremely rare in childhood, uric acid stone is most frequent, and the majority of cases of urate stone diathesis occur without true gout.

Now, although the precipitation of urates may be found in the urines of apparently normal healthy people, it is, in our experience, comparatively rare, and we believe that it is an indication, even in persons organically sound, at any rate of a temporary functional metabolic disturbance. One of us (H. W. B.) makes a rule to examine an early morning specimen of urine from nearly every patient he sees in private practice, and he finds that urates are more commonly deposited in the night or early morning urine than at other times; nevertheless, except in patients with allergic symptoms, it is rare to see a specimen with uratic sediment. Even in patients with acute seborrhoeic manifestations, in whom the urine is usually excessively acid, such a sediment is very uncommon. On the other hand, it is seen in patients with cirrhosis of the liver, heart failure with hepatic degeneration, and in acute infections such as pneumonia. In allergic diseases it is so frequent as to be almost constant at some period in the 24 hours, at least during the phase of active manifestations. In infantile eczema, urticaria, and the asthma-prurigo syndrome, for example, a reddish sediment is almost invariably noticed in the urine on cooling from time to time. It seems, therefore, that in allergic diseases there is an alteration in the colloidal state of the urine which predisposes to the deposition of urates.

The Ether Reaction.

This reaction was first observed by one of us (G. H. O.) in cases of cardiac failure with œdema. The test is performed as follows:—

To a few c.cm. of urine are added first a little of a 25 per cent. solution of sulphuric acid and then sufficient ether to form a layer above the urine about half an inch in depth. The mixture is then thoroughly shaken with the thumb over the mouth of the test-tube and allowed to stand. The layer of ether becomes frothy, but, if the reaction be positive, the froth in its lower part becomes viscous and opaque, like melted wax, after ten minutes or so. In strongly positive tests the tube of urine can then be inverted without spilling. The degree of positiveness is measured by the depth and density of the waxy scum beneath the superficial froth, and we would here emphasise that the test is one of degree only, because a slight reaction—i.e., the formation of a narrow band of opaque scum—is frequently found in apparently normal people. For this reason we do not wish to exaggerate the importance of the reaction; nevertheless it is one of great interest and deserves further study.

As far as our observations go, the reaction is always strongly positive during the acute phase of allergic manifestations but may disappear during the period of quiescence. We have, for example, found it very marked after anaphylactic shock and during the acute eruptive stages of urticaria and urticaria papulosa, though sometimes practically absent between the outbreaks. In migraine—and Dr. Moreland McCrea has confirmed this—it is positive during the attacks but may be negative at other times. In infantile eczema and the asthma-prurigo syndrome it may be well marked in practically every specimen of urine examined, but it is always most intense during the paroxysms of itching. It was strongly positive in the case of anaphylactic shock referred to above. We have also found it in hepatic disease, in acute febrile infections such as pneumonia, and in certain cases of active tuberculosis, and we have also seen it strongly positive in some cases of acute toxic eruptions from food poisoning and in generalised eczema due apparently to sensitisation to external irritants. It seems likely that there is a connexion between this reaction and the deposition of urates, both being probably dependent on an alteration in the colloid state of the urine.

If urine which gives a strong ether reaction is treated with a large excess of alcohol, a precipitate is obtained which is soluble in water. On shaking the aqueous solution with a third of its volume of ether a reaction apparently identical with the original ether reaction is given, suggesting that the latter is due to the presence in the urine of the substance precipitated from it by alcohol. The aqueous solution of this substance gives: (1) a positive xanthoproteic test; (2) a positive Millon's test; and (3) a negative biuret test.

It will be remembered that coagulable albumin was found in the urine of the case of anaphylactic shock; it was also present in a case of multiple scalds, and is sometimes found during acute paroxysms of hay-fever, in serum sickness, and in severe urticaria. Albuminuria, however, is rare in chronic allergic conditions, nor does the urine give a precipitate on half saturation with ammonium sulphate. It is probable, therefore, that the substance which appears to be responsible for the ether reaction is a deuteroproteose, the exact nature of which is being investigated.

Urinary Acidity and Concentration.

The acidity of the urine varies according to the particular phase of the "allergic cycle." In the period preceding an attack the free acidity is, if anything, raised, but the acidity falls as the attack proceeds and diminishes, and the urine tends to become neutral and sometimes strongly alkaline with a deposit of phosphates. During the acid stage the urine is usually concentrated, and very commonly deposits urates on cooling, although uratic deposits may occur in urines of only moderate acidity and comparatively low specific gravity. During the alkaline stage it is dilute; a diuresis after asthmatic attacks, for example,

has long been noted clinically. A patient may, in fact, during the same period of 24 hours at one time pass a strongly acid concentrated urine with a deposit of urates, and at another a highly dilute urine with a deposit of phosphates. Moreover, in several of our cases the deposition of urates has occurred, and the free acidity has been highest in afternoon specimens, whereas the early morning specimen has been dilute and alkaline.

Ammonia Excretion.

The ammonia excretion is one of the most remarkable features of the allergic state because it does not correspond with the degree of acidity. The normal ratio between the free acid and the ammonia-combined acid excretion varies according to Davis and Rixon⁴³ from 1:0.6 to 1:1.5, 1:1 being probably the normal average according to our own investigations. For the sake of comparison the figures obtained by one of us (G. H. O.)⁴⁴ in specimens of urine collected hourly from a normal person are reproduced. (Table V.)

* Per 100 c.cm. A.-c. A.=ammonia-combined acid.

It will be seen that normally the highest excretion of free acid and of ammonia-combined acid takes place in the early morning and evening, the so-called alkaline tide following meals. The ratio of free acid to combined acid was never greater than 1:1, and usually less. In persons with allergic symptoms the ammonia excretion is raised, often to an extraordinary extent, and the ratio is found to be abnormal at the period of and following the paroxysm. For example, a lady with asthma and lichenified eczema of the hands gave the figures shown in Table VI.

TABLE VI.

Total	132.6	580.6	1:2.6	1050	—

The asthmatic attack was nocturnal, and in the latter half of the night the free acid progressively diminished until 7 A.M. when the urine was alkaline, whereas the ammonia excretion lagged behind and at 6.30 A.M. a ratio of 1:7.0 was obtained. The diuresis accompanying the alkaline stage is well shown.

CASE 11.—A boy of 18 with asthma and prurigo. (Table VII.)

CASE 12.—Angeioneurotic cedema. (Table VIII.)

In Case 12 the attack of angeioneurotic cedema was already present when the investigations were begun, and adrenalin was administered after the first specimen of urine was examined. The figures show the very marked diuresis and the diminution of acidity with ultimate alkalinity, although the ammonia excretion remains high. Moreover, this progression towards the alkaline side is common to both asthma and angeioneurotic cedema and cannot be explained merely by

Urea, Creatinine, Uric Acid, and Chlorides.

The ammonia excretion, therefore, is raised in association with the paroxysms, and the other non-protein nitrogenous substances—viz., creatinine and uric acid—are also increased.

The diminution of the chloride content of the whole blood has already been noted. Examination of specimens of urine taken from a patient with active allergic symptoms at different times during the 24 hours has shown repeatedly that during the active stage there is retention of chlorides with a consequent low excretion of them in the urine, whereas after the paroxysms the excretion rises. This chloride retention has been shown to occur by Rackemann, Longcope, and Peters in serum sickness, and by Longcope and Rackemann in cases of urticaria. It is a well-known phenomenon in pneumonia and in other acute infections, such as scarlatina and typhoid fever. Kartmischew⁴⁵ and Urbach⁴⁶ have also emphasised its occurrence in pemphigus vulgaris and dermatitis herpetiformis. At the time of the post-paroxysmal rise in chloride excretion an estimation of the blood chloride may show higher figures than normal. This is illustrated in Case 13 (Table IX.).

CASE 13.—Spasmodic rhinorrhœa.

The specimen of blood was drawn at about 11.30 A.M., at the time of the high post-paroxysmal excretion of chloride. After the paroxysm the chloride that has been retained in the tissues presumably passes again into the blood (the chloride content of which is therefore raised) and is then excreted by the kidneys.

We have found complete absence of chlorides in the urine in (1) anaphylactic shock following an injection of pituitary extract which contained protein, (2) serum-sickness, and (3) cyclical vomiting; and marked diminution of the chloride excretion in migraine during the attack. In all probability it is a protective mechanism; the experiment of Richet and others on the prevention of anaphylactic shock in animals by the injection of sodium chloride support this view.

Retention of Chlorides Preceding and During Attack.

* Urates deposited.

† Mg. per c.cm.

In this case the first specimens were collected in the post-paroxysmal stage within 24 hours of the attack. In spite of the alkalinity of the urine there was a considerable excretion of ammonia. (The specimens were examined within a few minutes of being passed.) The chloride excretion was gradually rising. The later specimens were collected in the pre-paroxysmal stage, another attack occurring during the second day. It will be noted: (1) that these specimens deposited urates, (2) that the free acidity is high with a correspondingly high ammonia excretion, and (3) that the chloride excretion rapidly falls. The urea excretion is low—the patient being on a normal full diet—13.35 g. for the 24 hours, the normal figure being about 30 g. on an average diet.

The van den Bergh Reaction.

Recently one of us (G. H. O.) has sought for further evidence of disturbance of hepatic function by testing the van den Bergh reaction in our patients. The number of cases examined up to the present is too small for any definite conclusions to be drawn, but the results so far are probably of significance. (Table XI.)

These figures show the same rise in the quantity of ammonia-combined acid excreted that we have found in allergic cases, with a similar alteration in the ratio between free acid and the ammonia-combined acid. There is also the same diminished chloride excretion.

It is interesting to compare the figures obtained (a) in a child with cyclical vomiting, and (b) in a case of severe scalds. Davis and Rixon have found the same alteration in the ratio in cases of cyclical vomiting. (Table XV.)

TABLE XV.

	Free acid.	A.-c. A.	Cl.	Urea.	Ratio of free to comb. acid.	Vol.
Cyclical vomiting ..	6	71.4	0	1.7	1:7	15 oz.
Multiple scalds ..	18	224.4	0.05	1.62	1:7	—

In the latter case the urine contained albumin, uratic deposit with bile-salts, and biliverdin in large amounts. Here we see the same high excretion of ammonia-combined acid, the altered ratio and low chloride output; the involvement of the liver is shown by the excess of bile-salts and the bile-pigment in the urine.

The methods used in these investigations have been:—

For the Urine.

- (a) Free acid; direct titration.
(b) Ammonia-combined acid: Folin's method, using formalin and potassium oxalate.

- (c) Urea; hypobromite method.
 (d) Chlorine: silver nitrate and potassium thiocyanate in the presence of pure nitric acid, using ferric ammonium sulphate as indicator.
 (e) Uric acid: Folin's colorimetric method.
 (f) Creatinine: Folin's picric acid method.
 All the specimens examined were preserved with toluol from the time of passing.

For the Blood.

- (a) Amino-acid: Folin's colorimetric method, using sodium beta-naphthoquinone-sulphonic acid as reagent.
 (b) Chlorine as above.
 (c) Uric acid: Folin's method.
 (d) van den Bergh reaction: according to the original technique.

All these methods are described in Folin: "Laboratory Manual of Biological Chemistry," 1925; D. Appleton and Co., New York, with the exception of the van den Bergh reaction.

PRINCIPLES OF TREATMENT.

Our investigations have dealt with only one—the biochemical—side of the extremely complex problem of anaphylaxis and allergy, and by no means completely with that. We have been tempted to discuss the whole question, more particularly in connexion with the work of Dale and Laidlaw on histamine and histamine shock,⁴⁷ of Lewis and his co-workers,⁴ and of Roger and Garnier, Draper, Whipple and his collaborators, Haden and Orr, Binet, and many others on experimental intestinal obstruction. (An admirable review of this last subject, with full bibliography and personal observations, has recently been published by Binet.⁴⁸) Such a discussion, however, would be beyond the scope of this paper, and we will merely remark that the views on anaphylaxis, wound shock, and "protein sensitivity" tentatively put forward by Lewis,⁴⁹ and the biochemical investigations that have been made in cases of intestinal obstruction, more particularly by Haden and Orr,³⁹ may prove of great significance both in the elucidation of the exact nature of the allergic reaction and in its treatment.

In intestinal obstruction the most striking biochemical changes are the reduction of chloride in the blood—and, according to Haden and Orr, in the liver and to a lesser extent in the muscles—together with a lowered chloride excretion in the urine and later a rise in the non-protein nitrogen and of the bicarbonate in the blood. It is clear that the chloride is fixed somewhere, and Haden and Orr suggested, as Richet in his experiments on anaphylaxis had already done, that it combines with the toxin to form a non-toxic product according to the following formula:—

The resulting alkalosis is thus clearly explained, and the hypothesis is confirmed by the remarkable results obtained both experimentally and clinically by the injection of hypertonic saline to combat the symptoms of toxæmia and prolong life in intestinal obstruction. Our investigations show that in the allergic cycle there is, at one period, the same reduction of chloride in the blood, the same chloride retention, as evidenced by a lowered or absent excretion in the urine, and the same rise in the non-protein nitrogen of the blood. Moreover, although in the initial stage of the cycle there is a rise in the free acidity and of the ammonia-combined acid, this is followed by an apparent alkalosis which is accompanied by a diuresis. Since injections of sodium chloride are specific in overcoming the toxic symptoms of intestinal obstruction (other chlorides are useless, and of the salts tested only sodium bromide appears to have a similar effect), and are also capable of preventing experimental anaphylactic shock, one might expect them to be of value in allergic conditions, but we have not as yet employed them.

The principles upon which our treatment has been based are as follows:—

1. Seeing that, apart from cases in which it obtains access to the tissues parenterally—e.g., in hay-fever—the antigen responsible for allergic conditions is absorbed from the alimentary tract, and presuming

that either specific food proteins, the intermediate products of protein digestion, or toxic substances resulting from bacterial action on protein, are in question, we have instituted in many cases a more or less vegetarian dietary.

2. Believing that the high excretion of ammonia might be a protective mechanism, one of us (G. H. O.) administered considerable doses of sal volatile.

3. Since our investigations tend to confirm the views of those who hold that the liver plays an essential rôle in the drama of the anaphylactic reaction—as Roger has said, "the liver is the principal gland that intervenes in order to maintain or re-establish the chemical constitution of the organism"—we have sought to protect it both by a rational dietary and by prescribing additional glucose in order to increase the glycogen content of the liver cells.

4. To patients who show clinical evidence of exhaustion of the adrenal sympathetic system, as is usual in the chronic and severe cases of the asthma-prurigo group, we have given ephedrine hydrochloride.

We have purposely avoided employing the well-recognised methods of specific and non-specific desensitisation, and have seldom availed ourselves of the striking effect that real or artificial heliotherapy produces on patients with allergic symptoms.

The above principles may now be considered in more detail, but it will be understood that the exact line of treatment in a given case must obviously depend on the nature of the predominant symptoms, on their acuteness or chronicity, and on any special features peculiar to the case.

Diet.

It is sometimes said that dietetic treatment is of no account in many of the conditions under discussion—e.g., infantile eczema, papular urticaria, and the prurigos. On the other hand, both Rasch and Haxthausen are emphatic concerning the value of a lacto-vegetarian régime in Besnier's prurigo. The former goes so far as to say that it is the only method of treatment that gives any permanent relief, and he has found it successful not only in mitigating the prurigo but also in preventing the accompanying asthmatic attacks. We believe that the clue to a rational diet lies in a consideration of the functions of the liver in dealing with proteins and their derivatives. It is known that the liver fixes albuminous substances in its parenchyma (the "protéopexie" of Widal, Abrami, and Ivanesco), and that, if this function be interfered with experimentally, symptoms of shock supervene. In dogs with an Eck's fistula feeding with meat produces a state described by Fr. Fischler⁵⁰ as "Fleischintoxikation," thus illustrating the important function of the liver in protecting the body against foreign proteins. Its power of transforming the products of protein digestion—albumoses, peptones, polypeptides, and amino-acids—into the non-toxic urea is normally more important still. Finally, the liver renders non-toxic the products of bacterial action on undigested protein and, as Roger has shown, is capable of destroying bacteria themselves.

Now in those cases in which the antigen is absorbed from the alimentary canal we recognise (1) a group in which there is well-defined specific food sensitivity, and (2) a group in which this is not apparent. In the first group it is presumably the proteopexic function of the liver that is tested and, when allergic symptoms occur, fails. From the work of A. and M. Walzer⁵¹ on urticaria it would appear that the offending food substance is absorbed unchanged or incompletely digested and, reaching sensitised tissue, produces a local response due to antibody-antigen interaction. Their experiments are based on the well-known Prausnitz reaction. By injection of an area of skin of a normal non-sensitive person with the serum of one known to be sensitive to a certain food substance, and then feeding him with the food in question, an urticarial wheal is produced at the site of injection of the sensitised serum. Their observations are supported by those of Lewis and Grant,⁵² who experimented with a fish-sensitive person; but Lewis remarks that the active substance producing the

allergic response appears to be neither a coagulable protein nor histamine, and A. and M. Walzer observed that heating, baking, or canning the offending food protein, diminished, delayed, or prevented the response. This would suggest that the actual antigen is a specific substance that is fairly easily destroyed or changed. Moreover, A. and M. Walzer found that, whereas hyperchlorhydria tends to retard or prevent the reaction, achlorhydria tends to accelerate it, indicating that this specific substance is destroyed early in normal gastric digestion. We believe that the secretion of hydrochloric acid by the stomach may be an important factor in allergy of alimentary origin. We have not done fractional test-meals in a sufficient number of cases of the asthma-prurigo group or in cases of chronic urticaria to be able to state whether hypochlorhydria or achlorhydria are usual, but in light sensitisation of the adult type Howitt and one of us (H. W. B.) found very marked hypochlorhydria or complete achylia in 80 per cent. of cases.⁵³

To sum up: in cases of allergy due to specific food sensitiveness it would appear that the protein in question, with the specific substance producing the allergic reaction, may be absorbed unchanged into the blood stream. This is more likely to occur if the food is taken in its natural state, if the secretion of hydrochloric acid in the stomach is deficient, and if the proteopexic function of the liver fails.

In the second group, in which no specific food sensitiveness can be determined but in which the alimentary tract is clearly the source of the toxin responsible for the allergic symptoms, it is probable that incompletely digested protein-cleavage products derived from various food proteins, and bacterial toxins or the products of bacterial action on proteins, are absorbed, escape destruction in the liver, and produce the symptoms. In this case it is the detoxicating function of the liver that fails.

From these considerations it is clear that diet is of great importance but, apart from cases of specific food idiosyncrasies, it is probably not so much a question of the actual foods taken as of the capacity of the digestive organs and of the liver to deal with them. Hence a person who is compelled by experience to diet himself strictly under sedentary and trying conditions may often eat and drink with impunity when leading an outdoor and care-free life. The essential clue to the problem lies in the functions of the digestive organs and of the liver. We do not believe that there is any particular virtue in the lacto-vegetarian diet per se. In fact, the influence of cow's milk is sometimes definitely harmful, particularly in cases of infantile eczema, many of which improve promptly when cow's milk is excluded, and in older children with asthma and Besnier's prurigo, who are often given large quantities of cow's milk "to fatten them" in addition to a fully adequate mixed diet. The success of a lacto-vegetarian régime is, we are convinced, due to the reduction and simplification of the protein intake. What is important to realise is that the asthma-prurigo group of patients, with their highly developed and supersensitive nervous systems, are metabolically very unstable, and their ability to digest and metabolise proteins is limited. But their restlessness, both of mind and body, tends to rapid exhaustion, which is apt to precipitate the paroxysms of asthma or itching, and to induce the ketosis that characterises cyclical vomiting.

The rules of diet that we prescribe are similar to those advocated in cases of hepatic insufficiency, with such modifications that the nature and severity of the symptoms and the idiosyncrasies of the individual patient may require—viz., restriction of or abstention from meat and fish, and sometimes from eggs; an abundance and a variety of cooked and raw vegetables and fruit, the cellulose of which is of such importance; farinaceous foods, preferably in a form that compels mastication; cheese; fresh butter; glucose in preference to cane sugar. Meat and fish, when allowed, should be freshly and plainly cooked without fat (other than butter) or rich sauces. In addition

we have convinced ourselves of the value of sour milk with lactose in certain cases, particularly of light sensitisation and of dermatitis herpetiformis. Our most striking successes with this kind of dietary have been obtained in Besnier's prurigo, certain forms of eczema and prurigo in adults, light sensitisation, and dermatitis herpetiformis. Unfortunately the limitations of English cooking render such a régime unnecessarily difficult to enjoin and irksome to follow.

Ammonia.

One of the most striking features of the allergic cycle is the increased excretion of ammonia, whereby the ratio of free acid to ammonia-combined acid is altered. We are doubtful whether or not the high ammonia excretion is called forth merely in response to an acidosis. It occurred to one of us (G. H. O.) to try the therapeutic effect of administering ammonia in the form of sal volatile by the mouth. During the past nine months a large number of patients have been treated in this way, with 30 minims to 2 drachms of spiritus ammonie aromaticus, according to age, in a tumbler of water thrice daily before meals. At one time we prescribed it in a mixture with sodium sulphate, potassium bicarbonate, sodium phosphate, and sodium chloride, but we think it is more efficacious if given alone, freshly mixed with water. We have never seen any ill-effects from its use, except that a few patients have complained that it gave them indigestion. It is probable, in fact, that larger doses could be tolerated and, perhaps, would be more effectual. It should be taken, according to our experience, about half an hour before meals, and perhaps at bedtime.

It is difficult to estimate the value of sal volatile alone in the treatment of allergic symptoms, but our impressions are as follows:—

1. That in hay-fever, migraine, and urticaria its action may be very striking, both in preventing and aborting the attacks. In over a dozen cases of hay-fever it has appeared to be almost specific. Dr. Moreland McCrea has kindly tried it in cases of migraine with very successful results. In urticaria the effect seems to vary; some patients have done well, but in others it has proved disappointing.

2. In patients belonging to the asthma-prurigo group its immediate effect is less obvious but, given regularly over a long period of time, in combination with suitable dietetic treatment, it has seemed of definite benefit. The same may be said of cases of light sensitisation of the adult type.

We have not treated enough cases of asthma, uncomplicated by prurigo, to express any opinion as to its efficacy.

Glucose.

The value of glucose, with or without the simultaneous administration of insulin, in the treatment of various conditions is becoming more and more apparent; the literature concerning its uses is already formidable and cannot be reviewed here. Its cardinal virtue is, we believe, that it affords the simplest and most rapid method of increasing the glycogen content of the liver. Roger⁵⁴ and Fiessenger and Walter⁵⁵ have insisted that the glycogenic function is of paramount importance in the physiology of the liver. As Fiessenger and Walter point out, glycogen is essential (1) for the antitoxic function, since it allows of glucuronconjugation and of destruction of bacteria, which does not occur if the liver has been deprived of its glycogen by fasting; (2) for the protein function, since the destruction of amino-acids, of beta-oxybutyric acid, and of acetone bodies only takes place in the presence of glycogen; (3) for the lipopexic function; and (4) for the pigmentary function.

If, therefore, we ascribe to the liver a preponderating rôle in the defensive mechanisms of the body, it is clear that one of the chief therapeutic indications in hepatic disease and in allergic and allied conditions is to ensure an adequate supply of sugar, in order to increase the glycogen content of the liver cells. For this purpose feeding with glucose or, in cases of urgency, its administration by the intravenous and rectal routes, is the method of choice.

We have found it of especial value (a) in children belonging to the asthma-prurigo group, most of whom portray to perfection the characteristics of "the nervous child" so graphically described by Cameron,⁵⁵ who himself has long advocated its use; (b) in the thin hypotonic adult patient—usually female—in whom simple prurigo is so common a symptom; under-nutrition is here an important factor, and for it Izod Bennett⁵⁶ has rightly described glucose as "the most valuable fluid food available"; (c) in patients in whom there is unmistakable evidence of chronic hepatic insufficiency. We have also given it with striking success, usually in combination with sal volatile or sodium bicarbonate, in the prurigo of pregnancy, and as a preventive of the toxic effects of deep X ray therapy and of metallic drugs, such as salvarsan and sanocrysin.

Dodds⁵⁷ has shown that even 500 g. of glucose does not produce glycosuria in the majority of normal men, and Izod Bennett advises as much as 1 lb. per diem in severe cases of under-nutrition. We usually prescribe from 2 to 4 ounces daily in divided doses, both with and between meals.

SUMMARY AND CONCLUSIONS.

The points we would emphasise in the foregoing account of some of our investigations into the metabolism of allergic conditions are as follows:—

1. Certain phenomena have been demonstrated to occur with remarkable constancy in various manifestations of the allergic state; some of these have already been described by others in experimental anaphylaxis and in serum sickness, which is generally admitted to be truly anaphylactic in origin.

2. In the allergic state, whether it be intermittent, as in certain cases of urticaria, angeioneurotic oedema, asthma, or hay-fever, or whether it be more or less chronic with periodical exacerbations and remissions, as in Besnier's prurigo and infantile eczema, there can be recognised a definite cycle of events corresponding to the pre-paroxysmal stage, the actual paroxysm, and the post-paroxysmal stage. In this cycle the most striking features are: (a) The rise in the amino-acid content of the blood. (b) The fall in the chloride content, particularly of the corpuscles, due presumably to the chloride being taken up by the tissues. (c) The retention of chloride, so that its excretion is diminished or absent in the urine during the paroxysms, and its subsequent excretion in increased amount after the paroxysms, at which time the chloride content of the blood may also be raised. (d) The rise in the urinary excretion of ammonia, so that the ratio of free acid to ammonia-combined acid is altered, often very strikingly. (e) The deposition of urates in the urine in the pre-paroxysmal or paroxysmal stage. (f) The intensity of the ether reaction during the periods of active symptoms. (g) The diuresis, with decreasing acidity and sometimes marked alkalinity of the urine, in the post-paroxysmal stage.

3. The positive van den Bergh reaction of the biphasic type in a large proportion of the cases so far examined.

4. The similarity of the findings in a case of anaphylactic shock, in a case of multiple scalds, and in patients with definite hepatic disease.

It is possible that the raised amino-acid content of the blood in these cases results partly from: (a) the increased endogenous katabolism that occurs in anaphylactic and allergic reactions, as shown by the increased formation of creatinine; (b) from the relative temporary hepatic insufficiency caused by the damage to the liver cells, as evidenced by the positive van den Bergh test; (c) from the interaction of the antigen and the "defence-ferments" of Abderhalden⁵⁸ whereby amino-acids are formed. In any case, the positive van den Bergh reaction, the raised amino-acid content of the blood, and probably the increased ammonia excretion, the precipitation of urates, and the ether reaction in the urine, are indicative of a disturbance of hepatic function. It is likely that the increased ammonia excretion and the temporary retention of chlorides are protective mechanisms. A dietary based

on our interpretation of these findings, and the internal administration of ammonia and glucose, have proved of definite therapeutic value in many allergic cases.

ULTRA-VIOLET LIGHT AND SKIN CANCER.

By G. M. FINDLAY, O.B.E., M.D., Sc.D. Edin.

(From the Laboratories of the Imperial Cancer Research Fund, London.)

It has long been known that prolonged exposure to the weather may produce in the exposed skin changes which not infrequently terminate in cancer. These changes were first described by Unna (1896) under the name "Seemannshaut," since the condition is especially common in sailors. Similar changes often associated with atrophy are, however, by no means rare in the skin of old country people, one of the commonest sites for the lesions being, as Lenthal Cheate (1908-09) has pointed out, the skin over the posterior surface of the second metacarpal bone, an area which is also the commonest site for the development of cancer of the skin of the hand. In all countries where a white population is exposed to prolonged sunlight, keratotic changes in the skin are far from rare and in association with these keratoses, cancer of the skin not infrequently develops. In this country, according to Young and Russell (1926), fishermen, bargemen, and lightermen show an excess of facial cancer; agricultural labourers, farm servants, farmers and graziers, an excess of cancer of the hand. Among gardeners also, the amount of cancer of the hand is considerably in excess of what should be expected. The possibility that the sun's rays may play a part in this excessive production of skin cancer has not lacked supporters.

In France Dubreuilh (1907, 1915, 1920, 1925) in a number of publications has emphasised the aetiological importance of sunlight in keratosis and epithelioma of the skin, since these lesions, while rare in town-dwellers, are common in country folk. Bellini (1909) in Italy has reported similar findings.

In America Hyde (1900) points out that the coloured races suffer much less from skin cancer than the whites, among whom cancer of the face, neck, and hands is specially common in agricultural labourers. Corlett (1915) and McCoy (1920) also emphasise the importance of occupation and pigmentation in the genesis of skin cancer. In the latter's series of cases the distribution of cancer of the face, neck, and hands, according to the colour of the skin, showed that 62 per cent. occurred in blondes, 31 per cent. in chatains, that is, those with dark hair and little skin pigment, and 7 per cent. in the dark skinned.

In Australia Molesworth (1927) shows that rodent ulcer and epithelioma of the exposed portions of the skin are far more common than in this country. As in other countries with much sunlight, there is the same marked tendency for skin cancer to be common in the country and rare in the town. Rodent ulcer and epithelioma both develop in relation to pre-existing keratoses, more especially when the skin is poorly pigmented. Since those of Scottish and Irish descent have, as a rule, fair skins, the incidence of skin cancer of the face, hands, and neck is greater in these races than among the general population; while among Italians, on the other hand, skin cancer is very rarely seen. Quite recently Lawrence (1928) has suggested that in Australia the irritating action of the solar rays is accentuated by the relatively low humidity of the atmosphere. Among 20,000 patients with skin diseases seen in private practice there were 1374 rodent ulcers and 395 epitheliomata. Although the statistical value of these clinical observations may not be high, nevertheless the facts strongly suggest that sunlight, and more especially ultra-violet light, may play an important part in the genesis of skin cancer. Although no case of skin cancer due to the therapeutic use of ultra-violet light has yet been reported, Colquhoun (1927) has nevertheless recorded the production of multiple keratoses on the chest of a man, aged 27 years, who had received quartz light therapy for some eighteen

months, while Cheattle (1925) has noted that in skin "bronzed" by therapeutic exposure to sunlight there is very active mitosis in the epithelial cells situated above the basal layer.

Experimental Procedure.

In order to determine experimentally whether ultra-violet light had any carcinogenic action on the

FIG. 2.

Tumour from the back of mouse No. 14 ($\times 20$).

FIG. 1.

Tumour from ear of mouse No. 13 ($\times 20$).

skin, a series of experiments were carried out on mice.

The source of ultra-violet light was a quartz mercury-vapour lamp manufactured by the Hewitt Electric Company, Limited, of Hershham, Surrey. The lamp is fitted with a standard Y2 Ulviarc burner, functions on 200-300 volts, and has an amperage of 3.5. The spectrum of the mercury arc is said to cover a range from 2000 A.U. in the ultra-violet to 10,140 A.U. in the infra red; it is, however, deficient in red and infra-red rays. The mice, which were of the albino variety, were at first epilated with a solution of sodium sulphide on an area of the back between the shoulders, as is usually done in applying tar for carcinogenic purposes. After from one or two months exposure, there was no further need of any depilatory.

The mice were exposed to the light by placing them in a sanitary bin 15 in. in diameter, fitted with a false bottom of perforated zinc. The mercury-vapour lamp was placed on a wooden frame which fitted over the

Charts showing the Acceleration of the Carcinogenic Action of Tar by Exposure to Ultra-violet Light.

CHART 1.

1-20 = Mice tarred twice weekly and exposed to the mercury-vapour lamp for two minutes four times a week.
21-30 = Mice tarred twice weekly.

top of the bin in such a way that the rays of the lamp were directed downwards into the bin, the false bottom of which was 18 in. distant from the light.

In the first two experiments, the effect of combining ultra-violet light with a known carcinogenic agent, such as tar, was investigated. In the last experiment the effect of ultra-violet light alone was studied.

Expt. 1.—Thirty albino mice were tarred twice a week over a small area of the back with a known carcinogenic tar. Ten of the mice served as controls. The other 20 mice were exposed for 2 minutes four times a week to the mercury-vapour lamp. The results are shown in Chart 1. In this and the succeeding chart, the applications of tar are represented by dots, the commencement and growth of the tumours by the solid cones. Death of the animal is shown by a †, operation by a pair of scissors. From Chart 1 it will be seen that cancer of the skin occurred more rapidly in those mice which were treated with tar and ultra-violet light than in those treated with tar alone.

Expt. 2.—Leitch (1922) showed that if tarring was continued for from four to five months and then stopped, certain mice developed carcinomata a considerable period after the cessation of the tarring.

Twenty mice were tarred as before for four weeks, and during the same period ten were exposed to ultra-violet light for 2 minutes daily. Both tarring and irradiation were discontinued at the end of this period. In those mice which were tarred and irradiated, three tumours appeared, while in the mice which were only tarred no tumours developed.

The three tumours which appeared in the irradiated group were of a definitely malignant character.

The question of whether the accelerating action of ultra-violet light on tar carcinogenesis is due entirely to a local effect or to a combined local and systemic action is now being investigated experimentally.

Expt. 3.—In view of these results, experiments were undertaken to determine whether ultra-violet light alone had any carcinogenic action.

Twenty mice were used in the experiment, the exposure being 1 minute daily. Five months later the exposure was

CHART 2.

1-10 = Mice tarred twice weekly and exposed to the mercury-vapour lamp for one month.
11-20 = Mice tarred twice weekly for one month.

increased to 2 minutes daily and then after a further two months to 3 minutes, four times a week. In order to lessen the mortality, any mouse which showed a very severe reaction accompanied by ulceration escaped further exposure until the lesions showed signs of healing.

The general course of the experiment is seen in Chart 3. The first growth appeared in a mouse 217 days after the beginning of the experiment. At this time there were eight other mice alive, of which six subsequently developed tumours, two of these growths remained in the papillomatous stage, while in the other four mice there were six malignant growths and one papilloma. The mice dying before the appearance of the first tumour showed in their skins the changes typical of chronic solar dermatitis. The vessels of the cutis vera were dilated while the surrounding tissues

CHART 3.

P = papilloma. PP = multiple papilloma.
C = carcinoma. CC = multiple carcinoma.
† = death.

were infiltrated with round cells. The epidermis showed in some areas hypertrophy and irregular thickening with hyperkeratosis; in other areas reduction to a single layer of cells.

The following is a brief account of the growths occurring in the tumour-bearing mice.

Mouse 12.—A small papilloma at the base; there was no carnosus. The mouse died 18 days after the appearance of the growth.

Mouse 13.—A small wart-like growth first appeared on the anterior aspect of the pinna of the right ear. This grew slowly, finally ulcerating through on to the posterior surface.

of the ear. The structure of this tumour is seen in Fig. 1. Ten days after the appearance of the ear tumour a small papilloma was noted on the back; a second papilloma appeared a week later. These papillomata at first grew slowly; then after some six weeks the skin around the papillomata became thickened and a large horny growth resulted. The tumour was operated on and autoplasts made. Unfortunately, the tumour was infected and both autoplasts ulcerated out. At death, however, the left axillary gland was found to contain a metastasis. Histological examination of the tumour showed a canceroid very similar in character to those commonly produced in the mouse by tar painting.

Mouse 14 had a very similar history to that of No. 13. Three papillomata first appeared on the back; after progressing slowly for a time they took on active growth forming a large horny mass; in the meantime a warty growth had appeared on the anterior aspect of the right ear, gradually involving the whole of the pinna. Ten weeks after the first papilloma had been noted on the back a single small papilloma appeared on the dorsum of the pinna of the left ear. The growth on the back was operated on and autoplasted with subsequent growth. The tumour on the right ear had histologically the appearance of an epithelioma with keratinisation and cell nests. The superficial portion of the tumour on the back had a similar appearance, but the deeper portion had the characteristics of a small spindle-celled sarcoma. (Fig. 2.)

Mouse 15.—Three small papillomata first appeared on the skin of the back. The skin surrounding these growths rapidly thickened, forming a rounded firm mass about the size of a threepenny-piece. The tumour was removed at operation and two autoplasts made in the mouse. Both the autoplasts grew slowly. Six weeks after the operation the mouse was killed and one of the autoplasts was transferred to normal mice. Growth occurred in 1 in 20 of these mice. Histologically the original growth showed in the more superficial areas down-growth of epithelium with typical cell-nest formation and keratinisation. The deeper part of the tumour, however, had a more sarcomatous appearance, consisting of large spindle-shaped cells. It was possible, however, to distinguish all gradations of cell types from the typical epidermal cells of the cell nest to typical spindle cells. The question therefore arises as to whether this tumour is to be regarded as a carcinoma or a carcino-sarcoma. The same problem has arisen in the interpretation of many tar tumours. In the autoplasts the prevailing cell was of the large spindle-shaped type; keratinisation was absent.

Mouse 18.—A small papilloma first appeared on the anterior aspect of the pinna of the right ear. Subsequently the whole ear was involved, the cartilage of the ear being disorganised.

Mouse 19 had three papillomata on the back and one small one on the left ear.

Mouse 20 had two small papillomata on the back.

In neither of these animals was there evidence of penetration through the panniculus carnosus.

Of the seven tumour-bearing mice, therefore, three have developed papillomata, while four have had

growths which are of a definitely malignant type. In two of these four mice the malignant growths have been multiple.

Discussion.

The experimental evidence thus brought forward shows that mice exposed to the mercury-vapour lamp for a period of not less than eight months develop either simple papillomata or malignant epitheliomata. Further, when a known carcinogenic agent is at work on the skin exposure to ultra-violet light for a comparatively short period may lead to the rapid development of malignant new growths. These experiments, therefore, are in favour of the hypothesis based on clinical evidence that in man exposure to ultra-violet light plays an important part in the aetiology of cancer of the skin of the face, neck, and hands.

Conclusions.

1. By exposure of mice to ultra-violet light for a period of not less than eight months it is possible to produce papillomata and malignant epitheliomata of the skin.

2. When mice are tarred and exposed to ultra-violet light at the same time, the period necessary for the induction of cancer is shorter than when either tar or ultra-violet light alone is employed.

3. A series of mice tarred for one month failed to develop cancer, but when tarred and exposed to ultra-violet light for the same period three mice developed malignant growths.

BETHLEM HOSPITAL.—The annual report of Sir Lionel Faudel-Phillips, the treasurer of Bridewell and Bethlem Hospitals, states that the out-patient departments were closed at Michaelmas, 1927. The average weekly cost of maintaining patients was £1 17s. The new hospital buildings on the Monks Orchard Estate were begun in June, and good progress has been made. The appeal for the building fund has, so far, produced £45,000, but a further £50,000 will be needed if the new enterprise is to start free of debt.

AND

G. W. BRAY, M.B., CH.M. SYD.,
RESIDENT MEDICAL OFFICER, EAST LONDON HOSPITAL FOR
CHILDREN; LATE CLINICAL ASSISTANT, HOSPITAL
FOR SICK CHILDREN.

AT the out-patient department of a children's hospital many cases are seen with hypertrophied or infected tonsils, and the following study was undertaken to ascertain to what extent these contributed towards the child's symptoms and general ill-health. Our 500 cases were chosen from the out-patient

FIG. 1.

department at the Hospital for Sick Children, Great Ormond-street, and the Westminster Hospital. As far as possible only those cases who had been observed and their weight recorded for periods up to six months before and after tonsillectomy were included. Very great difficulty was experienced in getting such a large number of cases, as the vast majority ceased to attend hospital immediately after the

child had recovered from the operation. Of the 500 cases, 412 were observed for at least four to eight months continuously.

Sex-incidence.—Of the 500 cases, 277 (55.4 per cent.) were males, and 223 (44.6 per cent.) were females. This preponderance of males over females was noticed all through the records investigated.

Age-incidence.—275 of the 500 cases were between four and six years of age at their first visit to the out-patient department. This suggests that at this age infected tonsils give rise to their maximum symptoms. The age-incidence is shown in Fig. 1.

Chief Complaint.—In this series of cases the chief complaints were as follows:—

1. Respiratory group (145)—	4. Wasting group (70)—
Coughs, colds, catarrhs 129	Wasting 49
Asthma 16	Run down 11
	Debility 10
2. Alimentary group (104)—	5. Rheumatic group (43)—
Anorexia 46	Rheumatism 27
Vomiting 28	Chorea 11
Abdominal pains .. 8	Carditis 5
Bilious attacks .. 7	
Indigestion 6	6. Ear, nose, and throat
Constipation 3	group (30)—
Diarrhoea 2	Sore throats 13
Worms 2	Earache 12
Jaundice 1	Otorrhoea 3
Factor oris 1	Deafness 2
3. Nervous group (90)—	7. Urinary group (18)—
Nerves 74	Enuresis 14
Fits 4	Hæmorrhagic nephritis 3
Headaches 4	Pyuria 1
Restlessness 1	
Stuttering 1	
Habit-spasm 1	
Lislessness 1	
Night-terrors 1	

It was noticed that when the child was first brought to hospital the symptoms complained of in all but a few instances did not refer to the throat.

Effect of Tonsillectomy on the Child's Weight.—After the initial fall immediately consequent on the operation, there was a continuous gain in weight in all cases. This was not uniform, however, as some of the groups gained to a greater extent than others.

FIG. 2.

Fig. 2 shows the average weight before and after tonsillectomy. Examining this chart it will be appreciated that children sent to a convalescent home after tonsillectomy were on the average $1\frac{1}{2}$ pounds heavier at the end of six months than the less fortunate cases. We would stress the fact that the 92 children sent away were chosen because they had been actually losing weight during the six months prior to tonsillectomy. The remaining 408 had been either stationary or were showing but a feeble rate of gain.

Examining the various groups it will be noticed that Group 5, the rheumatic cases, showed the greatest improvement—that is, the average gain was 8.62 lb. The average gain shown by the other groups in the six months following operation was as follows: ear, nose, and throat group, 7.3 lb.; wasting and urinary group, 7 lb.; nervous group, 6.47 lb.; respiratory group, 6.27 lb.; alimentary group, 5.92 lb.

Discussion.

A review of the literature on this subject shows how very few papers include statistics. Moreover, most papers have been written by nose and throat surgeons, and their first observations have been at or about the time of operation. Analyses of the previous complaints and weight records are almost uniformly absent.

The benefits of tonsillectomy are outlined in a most convincing manner by Kaiser,¹ but his paper is open to the above criticisms. Barrington-Ward,² from the study of a large number of cases at Great Ormond-street, describes the problem and gives clear indications for the removal of tonsils. In a large number of cases of anorexia attending an out-patient department, studied by Bartlett,³ the commonest pathological condition found was that of septic tonsils and adenoids. Brennmann,⁴ in an admirable paper, pointed out the protean manifestations of nasopharyngeal infections, and has done much to awaken interest amongst paediatricians in this subject. Such interest is reflected in the fact that, at

the Hospital for Sick Children, Great Ormond-street, whilst 2886 tonsillectomies were performed during 1920, during 1927 there were 3909, an increase of 34 per cent.

Indications for Tonsillectomy.—Our cases, on examination, showed either very much enlarged tonsils, or, more commonly, moderately enlarged or buried tonsils with enlarged tonsillar glands. With such clinical findings was associated a history of (a) nasopharyngeal affections, or (b) general infections (e.g., rheumatism, hæmorrhagic nephritis) or metabolic upsets (e.g., vomiting, bilious attacks), secondary to these repeated tonsillar attacks.

Method of Tonsillectomy.—All the tonsils were dissected out, the majority (i.e., cases from Great Ormond-street) being done by Mr. G. E. Waugh's method. A few had had their tonsils guillotined elsewhere previously, and along with their recurrence was a return of the symptoms. To be of any use a complete dissection of both tonsil and lingual tonsil must be made. Almost every case was kept at least one night in hospital.

Time for Tonsillectomy.—Undoubtedly the spring, summer, and autumn are the best seasons for the removal of tonsils, as the child is able, after a short convalescence indoors, to get out into the fresh air and to pick up quickly any ground lost. During the winter months, with prevailing catarrhal infections and acute infectious fevers, the operation is likely to be severely complicated.

We suggest that our investigation has demonstrated the efficacy of tonsillectomy in selected cases. 500

children, who had come to hospital complaining of various symptoms, and who were found to have septic or hypertrophied tonsils, reacted in an almost uniformly satisfactory manner to tonsillectomy and rapidly gained weight. The gain in all cases was not equal; in fact, in some cases it was small, but in no cases noted did the child actually appear harmed, and in almost every case it was greatly benefited. In a properly selected case there is no single operation in children's medicine more successful or that shows such dramatic results as that of tonsillectomy.

In those cases where convalescence was arranged, despite the unsatisfactory condition of the children before operation when they were actually losing weight, a considerably more rapid recovery was made and a greater maximum gain shown. It would be ideal if every child could have a fortnight at least at the seaside or a similar complete change after tonsillectomy. The convalescent homes throughout the British Isles, especially those under the auspices of the Invalid Children's Aid Association, are fully alive to the difficulties of making a child thrive when sent with septic tonsils. One of the questions asked on the medical certificate demanded by the Invalid Children's Aid Association is: "Does the child require attention to teeth or tonsils?" At a number of homes, when a child has been admitted with septic tonsils, the parents are asked to sanction tonsillectomy in order to prevent a waste of convalescence.

Clinical and Laboratory Notes.

INTERLOBAR EMPYEMA.*

BY WALTER BROADBENT, M.D. CAMB.,
F.R.C.P. LOND.,

SENIOR PHYSICIAN TO THE ROYAL SUSSEX COUNTY HOSPITAL,
BRIGHTON.

THE most difficult empyemata to diagnose are those which arise in abnormal situations, such as the interlobar fissures. As there is considerable variation in the signs it may be of interest to quote a few cases.

Three Cases Described.

A gentleman, aged 30, was taken ill with a right-sided pneumonia. On the third day the left side was affected, and on the fifth he had pericarditis with friction all over the cardiac area, and a pulse of 130. After being desperately ill he slowly improved up to the nineteenth day, when his temperature began rising again. I saw him for the third time on the twenty-first day, his temperature having been 101° F. the two previous evenings. His right chest was moving well, though there were crepitations throughout the lower lobe, and there was still a little pericardial friction down the right edge of the sternum. The left chest moved very little. Over the apex and first space there was diminished resonance, poor rather bronchial breath sounds, and a few crepitations. In the second and third spaces weaker breathing. From the fourth space down louder breath sounds and more crepitations. On raising the right arm at right angles to the thorax there was a dull and silent area high up in the axilla about 1½ inches broad by 3 inches across, and below that crepitations. A needle put into this dull area revealed pus, and that afternoon a large empyema between the upper and lower lobes was drained by removal of a portion of rib high up in the axilla. The patient made an excellent recovery.

In another case the empyema, well shown by a radiogram, was between the upper and middle lobes on the right side. In that case there was actual dullness in the second and third spaces in front, with diminished resonance over the rest of the right chest. There was bronchial breathing at the apex, distant tubular breathing in the second and third spaces, below that weak breathing with coarse crepitations.

A third case was admitted under me in the 2nd Eastern General Hospital with what appeared to be a large empyema on the left side, there being dullness and silence from the

spine of the scapula to the base. Major A. H. Buck operated in the usual situation, but the amount of pus was unexpectedly small, and there was no improvement in the general condition, the temperature remaining hectic. A few days later I found that the lower part of the back was slightly resonant, but just below the level of the spine of the scapula there was an area of absolute dullness about 3 inches in depth. An aspirator needle inserted here withdrew much pus which, however, reaccumulated. Major Buck then removed a portion of the fourth rib between the scapula and the vertebrae and opened a large empyema between the upper and lower lobes of the lung. The operation was one of some difficulty owing to the depth of muscle. In this case the original empyema was evidently interlobar, and some of pus had leaked down over the lower lobe where it was found at the first operation. The man made a good recovery.

Besides these I have diagnosed three other cases of interlobar empyema, which have been subsequently cured by operation through the upper axilla. One of these was not preceded by pneumonia, but by a fall in which the left chest was severely bruised. In another case the patient, an old man, died after operation.

Physical Signs.

When pus collects in an upper interlobar fissure there may be dullness in the second and third spaces in front, or high up in the axilla, or a band of dullness at the level of the spine of the scapula. Resonance is diminished over the lower lobe from compression and congestion. On auscultation, over the upper lobe there is weakened bronchial breathing from pressure, over any dull band very weak breath sounds sometimes tubular, and, below that, weak and rather bronchial breath sounds with crepitations. If much pus collects the lower lobe may be so compressed that it is dull and almost silent, leading to the belief that there is an ordinary empyema. Unfortunately, the physical signs differ in every case. The best place to insert a needle is in the upper axilla with the arm at right angles to the chest, since this is the seat of election for operation, there being no muscle in the way, but, if an interlobar empyema has ruptured into a bronchus, the remaining pus is always near the root of the lung, and it may be too deep to be reached by a needle from the axilla, and one may have to be used in the interscapular region or in the dull area in front.

Of empyemata between the middle and lower lobes on the right side I have only diagnosed two. In

* Being remarks made in a discussion at the Medical Society of London on Oct. 22nd. (See THE LANCET, Oct. 27th, p. 563.)

neither of them was the heart displaced to the left. The right chest was more or less dull all over. From the apex to the third space breath sounds were of rather distant bronchial character with fine crepitations. In the fourth space from the nipple out to the mid-axilla there was louder bronchial breathing with no crepitations. Below that breath sounds were much weaker, but crepitations could be elicited on deep breathing. Over the back breath sounds were bronchial down to the middle of the scapula and weak below that, but crepitations could be heard almost down to the base with a deep breath. In one a radiogram showed the right chest opaque with a lighter area from the apex to the third space, and a little light patch at the inner side of the base just above the liver. It also showed that the heart was not pushed over. I had a needle put into the fourth space in the anterior axillary line, where the bronchial breathing was loudest and where there were no crepitations. Pus was found, a portion of the fifth rib in the anterior axillary line was removed, and a large interlobar empyema was opened, the patient making a good recovery. In the other case the empyema burst into a bronchus before operation, and the patient died.

A very rare position for an empyema is between the mediastinum and the lung, the lower lobe of the lung being adherent to the chest wall. In the only case that I have seen the whole of the left lower chest was dull and silent, but the heart's apex was to the left of the nipple line. The temperature and the blood count indicated empyema. Needles in the ordinary area failed to find pus, but one just external to the angle of the eighth rib struck it. Later a piece of rib just beyond the angle was resected, and a large empyema opened which extended forward to a depth of 8 inches. It was bounded externally by the lung, which was completely adherent to the parietal pleura and collapsed.

Another rare position is between the base of the lung and the diaphragm. After a right-sided pneumonia the temperature pointed to empyema, but, though the lower half of the chest was wanting in resonance, it was not so dull as in empyema, and redud crepitations could be heard nearly to the base, but I found a dull and silent area about 3 inches broad over the lower ribs in the posterior axillary region. A needle inserted here withdrew pus, and a largish empyema was found between the lung and the diaphragm, with the lung firmly adherent to the chest wall above it. One point should be remembered in children—that breath sounds can often be heard distinctly through quite a lot of pus. If there is flat dullness it is always safer to explore.

Treatment.

As to the treatment of empyema, in the interlobar cases it is advisable to stitch the lung to the parietal pleura before opening, unless it is already adherent, and it is necessary to leave in rather a long tube to get good drainage. As mentioned before, the upper axilla is the easiest place for operation in those in the upper fissures, if pus can be obtained there, and the right anterior axillary line at the level of the nipple for one in the lower fissure.

In an ordinary empyema, especially if it is a large one, I strongly advocate aspiration one day, removing as much pus as possible, and operation the next day. This lessens shock, and gives a chance for the pleura to become adherent in the upper part and reduce the size of the cavity. It is not, however, a good thing to aspirate an interlobar one, since the larger they are the easier they are to open. Cure is much hastened if no air is allowed to enter the empyema after it has been opened. A good-sized tube should be used, not passed much into the pleural cavity, and the layers of the wound should be fixed tightly round this by purse string sutures. Strips of strapping put round the tube beyond the dressing and fixed to the skin help to keep it in position. The end of this tube is connected by a small piece of glass tubing to a long rubber tube leading to a bottle beneath the bed, or,

better still, to a suction apparatus, such as that described by Dr. F. J. Poynton. If the tube should get blocked the end should be clamped by a spring clip before taking off the glass portion. Then the patient should be told to cough, the spring clip being released in the expiratory stage of the cough and put on again with the inspiratory stage. Sometimes sinus forceps may be necessary to clear the tube, and this should be followed by irrigation with eusol.

SKIN IRRITATION UNDER ULTRA-VIOLET RADIATION.

BY STANLEY VAN S. BOYD, M.R.C.S. ENG.

IN over four years' constant practice of treatment by ultra-violet radiation I have had a large number of patients who have exhibited irritation of the skin in greater or lesser degree. While in some cases this irritation has merely been provocative of humour, in many the complaint has been bitter. Guided by the reaction of the sweat, which is, of course, secreted in considerably increased amount owing to the hyperemia induced by the rays, I have been in the habit of recommending patients who suffered from this trouble to bathe their skins with alkaline lotions. In the milder cases this was effectual. The irritation being allayed, successive doses of radiation rapidly induced such resistance in the skin that the pruritus ceased to occur.

This year I had under my care at one and the same time three patients in whom this irritation was so severe that radiation treatment had to be abandoned. I had long sought for some common factor, in complexion or texture of the skin or what not, upon

which I might depend to predict the probable occurrence of this distressing complication; but the fact that neutralising the perspiration gave relief to milder cases suggested the possible value of an investigation of the alkaline reserve in the severer ones. The results of these inquiries are to be seen in Table I. All of these estimations, and those reported in Table II., were carried out for me by the

Harrogate Clinical Laboratory, and I wish to acknowledge my indebtedness to Dr. F. B. Smith for his invaluable assistance in this matter.

It will be seen that all the evidence in these cases pointed to the existence of a functional depletion of the alkaline reserve. The absorption power of the blood for carbonic acid was either below or at the low limit of normal. All the urines were highly acid to litmus, and when titrated against deci-normal sodium hydrate—evidence which was supported by the pH value. The ammonia-urea-nitrogen ratio was estimated as an indication of the proportion of total acidity which might be attributed to amino-acids. An alkaline tolerance test was undertaken so that any condition of true acidosis, as opposed to functional variations, might be revealed.

Case 1.—The patient was placed upon a course of alkalisng medication, and although the period of testing unfortunately could not be prolonged, very considerable increase of tolerance of ultra-violet radiation was observed. Before alkalisng, a dose of 20 seconds, from which all rays shorter than 2900 Angström units had been filtered, had produced an irritation so severe as to bring on a syncopal attack; while afterwards an unfiltered dose from the same lamp of 45 seconds produced no irritation whatever.

Case 2 proved very different. Up to seven years ago there was no sensitiveness to strong sunlight at all. The patient then had an operation for the removal of the appendix, and a further one for mammary abscess. Immediately after this she observed that the least exposure to sunlight produced a papular rash with severe irritation. She had been to London, where her physician clearly considered her's might be a case of food allergy. She was first placed on a short fast, and then fed on single articles of diet, in order to discover to what foods, if any, she had become sensitised. At the same time, intravenous peptone injections were given, and these appeared to her to do her more good than anything. Her relief had been, I found, only temporary.

When I first saw her I found she had herself observed that a bruise would produce a purely local manifestation of the rash; and also that an immersion of her feet in sea water had given her a similar result wherever the sea water had bathed the skin. Alkalisng proving ineffectual, some of her serum was incubated with peptone-agar, after the method recommended by A. G. Auld for asthma. She had increasing doses of this serum over a period of three months, and though able to take ultra-violet light better than before her treatment, I regret to have to report that she retains apparently in full her sensitiveness to sunlight.

Case 3 was that of a patient who consulted me regarding rheumatic pains in the neck, shoulders, back, and knees, and whom I found to be showing nodular fibrous thickenings in the areas affected. A course of autogenous vaccine had been given her without much benefit. As we frequently find that such patients may prove responsive to their vaccine after a course of radiation, I attempted this treatment, but the itching was so severe that I had to desist. I found on inquiry that for five years there had been severe irritation of the skin on exposure to the air immediately after the daily bath, and this had been so severe that at times relief was sought by the use of aspirin.

I recommended a period of auto-nutrition, with colonic lavage, and estimations of the urine were made from time to time. This treatment is instituted so that while being fed on nothing but water, the body may have an opportunity of selecting the amounts of the various food elements required for the metabolism from the storage depôts, and because it has been found that under these conditions abnormal deposits, such as fibrositic nodules, are absorbed or dispersed most rapidly. The fast in this instance lasted for 324 hours, and, as will be seen from the summary shown in Table II., the acidity of the urine steadily decreased from 91 to 39.0.

Both purposes of the treatment were attained. The rheumatic pains were completely relieved, and the patient was able to take ultra-violet radiation without irritation. Incidentally the after-bath trouble disappeared also.

The practical result of this inquiry has been that a routine examination of the urine is made before treatment is undertaken, and in such cases as show marked acidity I prescribe an alkaline mixture, and, if possible, increased exercise in the open air (this, by augmenting ventilation, induces an increased CO₂ excretion), in order to prevent such irritation as might arise from deficient alkaline reserve.

Harrogate.

Medical Societies.

A CONGRESS OF RADIOLOGY

THE British Institute of Radiology, incorporated with the Röntgen Society, arranged a congress on radiology for Nov. 14th–17th. On Friday, the 16th, the subject of discussion, under the chairmanship of Sir HUMPHRY ROLLESTON, was

THE VALUE OF THE OPAQUE MEAL IN DIAGNOSIS.

Sir THOMAS HORDER maintained that, despite the inestimable contribution of X rays to diagnosis clinical medicine still had a legitimate sphere of action, and that to parcel out the patient among radiologists, bacteriologists, and biochemists was not to do the best possible thing for him. Patients were coming to believe that there was a difference in essential value between facts elicited by instrumental and by clinical investigation. The only difference was, in reality, in the degree of facts, in their interpretation, and in their relation to other facts. The crux of the decision lay in determining what was and what was not pertinent to the main issue. The great art of diagnosis did not lie in the accumulation of a vast quantity of data, nor in establishing a superiority for one set of data obtained by one particular method, but in taking a survey of all data and selecting the essentials. The contribution made by radiology towards the diagnosis of alimentary disease had been quite incalculable, and would be even greater if the standard of radiograms were raised. Numbers of indifferent radiograms might well be exchanged for one or two good ones, and greater care should be exercised in selecting cases for opaque meal examinations. Partial investigations should be rare; the number of fallacies increased with every limit imposed upon the examination. It was by no means true that the better the radiogram the easier the interpretation; the contrary was the case. As finer and finer variations were demonstrated the meaning of the observations became wider and demanded the utmost forbearance in its reading. Far better be afraid to "rush in" than be afraid to forbear. Radiologists should beware of theorising in their reports; what the clinician asked of them was an opinion on the present state of the patient.

Spasm of the œsophagus might be so chronic and tight as to appear malignant when it was not, and the most skilful technician might fail to get a bougie through under deep anaesthesia. A routine investigation of an opaque meal should always include watching the bolus from the pharynx to the stomach, or a cardiac growth might be overlooked. Localised and extraordinarily persistent spasm was also common in the stomach and duodenum and was often functional; the terms "hour-glass," "cascade," or "cup and spill" carried with them fixed notions which too quickly determined the report. Radiologists could give the greatest help of all in carcinoma; clinicians wanted the earliest possible suggestion—lessened motility, deformity in peristaltic wave, and so on—and could not afford to wait for proof. The radiological picture was not of great significance in visceroptosis; it was unhealthy functioning and not faulty position that underlay symptoms. He questioned whether reports claiming to diagnose "colitis," "gastritis," or "abnormality of the mucosa" did not strain the method past its present possibilities and do it a disservice. Delay in emptying was no more proof of disease than variation in length and calibre. Radiology helped very little with diseases of the appendix, chiefly because of its complex pathology.

Radiology and the Surgeon.

Mr. A. J. WALTON recounted the help he had gained from radiology and emphasised the importance of the radiologist. The most modern equipment was useless in the hands of an untrained man. Too often,

also, cases were sent for X ray when the most superficial clinical examination would have made it clear that such an investigation was unnecessary. A second fault was that doubtful cases were provided only with one poor film, unaccompanied by a report, which was not only useless but positively dangerous, as it caused wrong diagnosis and a false sense of security. A careful investigation by a well-trained man and accompanied by a detailed report was of inestimable value and almost essential to diagnosis. The report must be regarded only as one piece of evidence among many, and should include a detailed account of findings as well as the conclusion. The surgeon, also, should let the radiologist know his observations. The films were of secondary value often to the screen findings; a film was a single photograph of a cinematograph performance—a fact which was often forgotten by the lay and medical public. Diagnostic difficulties were probably only temporary, and the majority of them to-day only arose when the investigator was relatively unskilled.

In gastric ulcer the history would give a 90 per cent. accurate diagnosis while radiology also gave 90 per cent. accurate results; the two did not exactly correspond, so that between the two methods a very small doubtful percentage remained. Great difficulties in diagnosis were encountered in visceroptosis in women, simulating ulcer; gastritis in middle-aged men simulating carcinoma; chronic pancreatitis simulating ulcer or cancer; penetrating ulcer of the lesser curvature and carcinoma of the stomach. In these cases coöperation between surgeon and radiologist was of immense value. Of great importance also was radiological investigation of the rest of the body, for chronic pulmonary tuberculosis might simulate gastric ulcer. The clinical history of duodenal ulcer was usually definite, but gall-stones might simulate it and require radiology for their differentiation. In the future, X rays would be most helpful in determining whether the ulcer should be treated medically or surgically. If there were only slight irregularity of the cap or hyperperistalsis, the ulcer might be more of the nature of an acute erosion and susceptible to medical measures. The scarring of an old ulcer might give appearances indistinguishable from those of active ulceration. The frequency of duodenal diverticulum was not fully recognised, but the X ray picture was unmistakable. Superficial gastro-jejunal ulcer could not always be distinguished from the irregularity of an anastomotic opening, but radiology was of great value in confirming a diagnosis. Distinct obstructions in the small intestine might be clearly revealed. Entry of the barium meal into the appendix and changes in mobility might indicate degenerative rather than inflammatory changes. On the whole, the value of the opaque meal depended entirely upon the investigator and on the degree of coöperation between radiologist and clinician.

The Radiologist's Point of View.

Dr. A. E. BARCLAY said that surgery and radiology must progress hand in hand, and there was still plenty of room for increased accuracy in diagnosis and treatment. The classical symptoms of disease known to Osler had been for the most part swept aside in the realisation that a defect in one section often showed its first symptoms in some quite distant part of the abdomen. Many gastric conditions differentiated 25 years ago were no longer recognisable as clinical entities, and their exciting cause was seldom in the stomach itself. Gastro-intestinal symptoms were perverse and unreliable guides to facts within the abdomen, and the surgeon would accept the opinion of an expert radiologist against the clinical signs. No elaboration of apparatus and no perfection of technique alone, however, would give accurate results. The man behind the gun made all the difference. Those in authority had not realised the vital importance of obtaining the services of the best men for this specialised work. Those who had taken the diploma course should be saved from many errors that pioneers had made. If clinical, radiological, and operative

diagnosis were compared it would be found that the two latter were far more often in agreement than the two former. Sometimes the radiologist was blamed for not having reported an ulcer or neoplasm found at operation months after he had made his examination; every X ray of an ulcer case might well be labelled "valid for three weeks only." X rays had shown how different were the living conditions in the alimentary tract from those of the post-mortem room, and that tone was closely associated with the emotions and with general health. The change brought about by radiology was exemplified most clearly in the diagnosis of oesophageal conditions, of which the symptoms and signs were misleading, and the only previous diagnostic aid had been the blind barbaric bougie. With the exception of adhesions and a few rarities, X rays of the stomach revealed only two pathological conditions—ulceration and malignancy—and had shown that in earlier days the stomach had often been unjustly blamed for conditions which had their origin in other organs. The patient radiologist could now detect the smallest lesions, and only those in the pyloric antrum escaped his investigation. The duodenum had been shown to be the seat of ulceration as prevalent as that of the stomach, but in many cases the clinical picture did not correspond with the radiological. Definite diagnosis should be confined to cases where the crater had been demonstrated—a tedious and skilled business. Lesions of the small intestine were rare, but the clinical signs were so vague that a diagnosis was quite impossible and the radiologist alone could give the clue to site and obstructive nature before acute symptoms prejudiced the chance of operative success. Radiological diagnosis might be better with the old semi-solid meal than the modern fluid one, which was less readily obstructed. For appendicular examination a fixed routine was supremely important. The three points in identifying a chronically inflamed appendix were ileal stasis, fixation on careful manipulation, and pain on pressure over the appendix. In palpation the radiologist alone could be certain of putting his finger straight on the right spot before the patient had time to resist. In acute or semi-acute appendicular trouble there might be no shadow in the terminal ileum after five hours, but a fair shadow in the ascending colon, and perhaps beyond. If an appendix retained the opaque salt days after the cæcum had emptied, it was obviously not doing its duty. Taken all in all, the radiological diagnosis of appendix trouble was vastly more reliable than the clinical.

The signs of growth in the large intestine were obstruction, fixation on palpation, and filling defect, and workers were apt to rely too much on the first. In the absence of spasm quite large growths might be missed. Sources of error in the detection of a filling defect were partial filling and scybala not impregnated with the salt. Diagnoses of colitis should be very rarely given in the absence of Crane's "string sign" and a few other fairly definite appearances. Diverticulitis, however, was usually obvious.

The diagnosis of lesions of the large intestine was the least satisfactory of all, but on the whole so valuable was the information obtainable that the clinician who did not use the opaque meal was as negligent as a mariner who set out without a compass. The work should be done by a specialist who had had wide previous experience of medicine and pathology and with time to examine and re-examine. Good X ray work was expensive and valuable; cheap work had brought much unnecessary discredit on the method.

Discussion.

Dr. H. E. GAMLEN emphasised the importance of having a qualified radiologist, and said the diploma should be made more difficult and should include adequate knowledge of radium and of pathology, and candidates should give evidence that they had followed up cases from beginning to end. Clinicians made matters very difficult for the radiologist by sending him no information and not telling him the after-history of the cases.

Dr. GILBERT SCOTT said the radiologist must use to the full his clinical and radiological experience, powers of deduction and sound judgment; he was a diagnostician and not a technician. He described the contrast between early opaque meals and modern technique, whereby a detailed examination of the stomach could be made in five minutes with a 90 per cent. accuracy. Diagnosis was now based on direct evidence, and the photograph was now used more as a record than a diagnostic aid in a mobile organ like the stomach. The lesion was detected by manipulation on the screen; about 3 oz. of a palatable mixture was first given and smeared all over the stomach by means of a hand on the abdomen. This revealed the antero-posterior wall, which the full meal examination did not. Differences in radiological and surgical findings were more often due to the radiologist "finding" a lesion and the surgeon failing to find it than vice versa; this was an error of the inexperienced radiologist who took normal variations for pathological lesions.

Dr. L. A. ROWDEN said that his diagnoses were made as much on his clinical examination as on his X rays. He never took more than one patient in one day for an opaque meal, and the investigation lasted from 10 A.M. to 5 P.M. He began by screening the whole body, then passed on to the Scott-Barclay gastric examination, then to painting the duodenum, and then to the full meal and the follow-through. His meal was palatable, wholesome, and nourishing, and he never used barium.

Dr. G. E. VILVANDRÉ said he had learned much in the theatre and post-mortem room. Screen examination was invaluable, but good plates at frequent intervals were also necessary to reveal small carcinomata. The eye could miss things which the photograph fixed. The indefinite "chronic appendix" could be diagnosed by X rays; tenderness, concretions, fixation, and calcified glands were all useful diagnostic points. Many "silent regions" should not be silent, but the sigmoid was a very difficult part to examine and a button-like early growth would not show on the screen. Therefore any small abnormality should be pointed out and investigated by sigmoidoscopy. The same applied to the oesophagus.

Dr. J. R. WYLLIE gave statistics of the 364 barium meals administered at the Miller General Hospital during this year. Seventy-five gastro-duodenal cases had subsequently been operated upon; 23 had proved to have gastric ulcer, 29 duodenal ulcer, 8 carcinoma, 2 gastric and duodenal ulcer, and 1 adhesions, giving a percentage of organic lesions of 98 and of absolute accuracy of 88.

Dr. G. B. BATTEN said that when surgeon and radiologist differed about the presence of a duodenal ulcer he believed the latter. He thought there was a happy mean between Dr. Rowden's lengthy technique and the rapid American style where every possible lesion had been tabulated and numbered and 66 barium meal investigations were made in an afternoon. There was a danger of causing hæmorrhage if ulcers were too freely manipulated.

Dr. R. C. RODGERS said that many cases sent up as gastric or duodenal ulceration turned out to be chronic appendicitis. If there was delay in the cæcum he gave an enema, and if the cæcum was found empty with two or three dots round about it the appendix was usually pathological; his percentage of accurate diagnoses had been fairly high.

Mr. P. T. CRYMILE said that the radiologist of the future would be an expert gross pathologist. Surgical findings must not be taken as scientific fact. Many ulcers were now found in the second part of the duodenum, though formerly they were believed to be rare in this portion, and multiple ulcers were more common than single. He had had some help from emptying-rates; a seven-hour gastric retention persisting for some months justified laparotomy.

Dr. JOHN MUM said that it was very difficult to evaluate this method on percentages, as so many cases did not come to operation. The value depended entirely on the impression given to the clinician;

therefore reports should be carefully sent up. Radiologists were specialists and should stick to their specialty; it was for the clinician to ask questions and make the diagnosis. He had collected from the literature 15 radiological signs of appendicular disorder and 12 of them were absolutely worthless, although repeatedly quoted. He asked for contributions to form a pathological teaching museum for students of radiology, so that the museum specimen and the X ray photograph could be displayed side by side.

Dr. STANLEY MELVILLE said that the clinician was apt to forget that the radiologist was talking only in terms of shadows. After five weeks' alkali treatment an ulcer would disappear, but that was no justification for stating that the ulcer was healed. It was for the clinician to say when a lesion was healed; the radiologist merely reported that at a given time there was no radiological sign of ulceration and that was where his business ended—or ought to end.

Mr. WALTON, replying, commented on the remarkable agreement manifested throughout the discussion; criticism lay not against radiologists, but against the public interpretation of radiology. Ludicrous statements were made by people who produced and relied on single films. There was no discussion on the value of radiology properly carried out. Of all silent areas the rectum was the most silent and must not be forgotten. It was most essential that some senior person should decide which cases were to be sent for X ray examination.

Dr. BARCLAY also replied.

PUBLIC HEALTH CONGRESS.

LONDON, NOV. 19TH-24TH.

BRITISH municipal associations met in congress on public health administration this week at the Agricultural Hall, London. The first act was the formal opening of the exhibition by Mr. NEVILLE CHAMBERLAIN, Minister of Health. After Sir FREDERICK WILLS, chairman of the organising committee, had explained the origin of the Congress as an offshoot from the Congress and Exhibition of Public Works, which had become too occupied with roads to deal faithfully with the public health aspect of its duties, Mr. CHAMBERLAIN spoke of the value of the exhibition to exhibitors and visitors alike, enabling them to compare notes on what the manufacturers had to offer to local authorities engaged in public health work and what the local authorities needed. He illustrated by statistics the wonderful work of public health measures in maintaining an increasing population of the country despite the enormous decrease in birth-rate. Some people deplored an increasing population, but he believed warmly in the British race, and thought the more there was of it the better. He outlined the proposed reform in the poor-law and the greatly increased responsibility and power thereby given to local authorities for assisting the public health.

In the afternoon Sir ARTHUR STANLEY presided, when Sir GEORGE NEWMAN gave an address on

The Purpose of the Public Health Service.

Its purpose, he said, was continually changing, and there had been a public health purpose before there had been a public health service. Its object had been to prevent "famine-pestilences," which were traced to unsuitable food and the nuisances consequent upon the flooded state of the country. The solution, therefore, had been more and better food and drainage. The first stage in the development of the public health service had been land drainage and agriculture which, although a thousand years old, was an ever-new problem. The next stage had been one of opposing by regulations, as far as possible, the diseases known as "leprosy" and "the plague." Leprosy was the first disease against which a by-law had been passed

in England, and the first Sanitary Act had been directed against the plague. At this time arose the "Commissioners of Sewers"—a position which had been Sir Thomas More's first public appointment. In the seventeenth and eighteenth centuries small-pox, typhoid, influenza, and cholera had directed the purpose of the public health services towards the channels of infection—the environmental factor. The study of typhoid had led to the establishment of adequate water-supplies. In our own period—the "golden age of bacteriology" introduced by Pasteur and Koch—the centre of gravity had moved from channels to causes, from the environment to personal hygiene. Between 1870 and 1910 no less than 20 great diseases had been traced back to their organismal cause. The two great fundamental purposes of all public health work must be the improvement of the environment of man and the care of his personal bodily health. England had unquestionably the most complete and comprehensive public health service that there had ever been, and the State intervened on this enormous scale because it had now been realised that the purpose of that service was no less than the survival of man and the increase of his capacity. Nations which had disregarded the communal health were not here to give evidence. No single factor had changed the lives of races more than disease. Unless man conquered disease, disease would conquer man. Last year England had saved 37,000 babies over and above the average number saved in 1910, thus proving that life could be saved hand over fist. Not only were lives saved but also man was being taught how to live a physiological life. This amazing triumph had come about largely because medical science had captured for its own use a great many non-medical agencies and powers. The speaker instanced the thermometer, steam for steam-disinfection, the prism and ultra-violet rays, analgesic drugs and anaesthesia, Liebig's work and proprietary synthetic foods, photography, the internal-combustion engine, X rays, and radium. It had captured also the social life of the people; health was the most popular subject of government and was "news." Rapid communications enabled us to transmute scientific discovery so that it became the property of every man, woman, and child. One thing not exhibited was the National Health Insurance, a service based on the guild system of the ninth century. He quoted details of the expenditure on social service, which in 1901 was 31 million pounds and in 1926 was 308 million—figures unprecedented in the history of the world.

At the morning session on Nov. 20th the subject of discussion was

Research in Relation to Public Health.

Sir ARTHUR ROBINSON took the chair and spoke of the importance of the research worker in all the problems of public health, and of the great and immediate interest of the State in research.

Sir WALTER FLETCHER described the steady evolution of public health policy from negative morality, "Thou shalt not," to positive morality, "Thou shalt"; from punitive codes to a great constructive policy of service, from opportunism to the principle of maintaining and developing all the conditions of life which made for health and efficiency. That progress, he said, had been due to the steady application of science as science had developed. The public health official was performing an art because he was dealing with human beings; before he could get the public with him he had to be not only the exponent but also the interpreter of science. There was no simple relationship between research and its application in public health work; there must be a lag, due partly to deficiencies of interpretation, partly to imperfections of the machinery of Parliament, the vehemencies and exigencies of party, partly to social customs and prejudices and the efforts of cranks, and partly at times to physical fear. Fear, indeed, often accelerated reforms, as it had at the time of the two cholera epidemics in 1848 and 1866, when the first Public Health Act and the

Sanitary Act had been saved from almost certain disaster by the outbreak of disease.

The first branch of science to shape and model public health policy had been bacteriology; all the great triumphs of modern public health were dependent on patient and unseen laboratory work. They were now supposed to be the obvious operations of common sense, but the common sense of to-day was the laboratory discovery of yesterday. The application of bacteriology had perhaps gone too far in some directions, for instance, in terminal disinfection and in some of the modern rigour of plumbing requirements. In other directions it had not gone far enough. The milk-supply was an instance where, if the public could only have realised the extent of the evil, they would have made it a chief political issue. The story was a discreditable one, however told; political difficulties and other matters had long delayed the great boon of clean milk that bacteriology had to offer. There were curious local differences in the way the resources of science were applied. Protection and immunisation against diphtheria were greedily applied in one great city and almost untouched in another. In too many directions, moreover, bacteriological science had no help to give, for instance, in virus diseases.

Other sciences also had developed, notably physiology. While this country had conspicuously applied the work of foreign bacteriologists, it was equally conspicuous for producing physiologists and neglecting the applications of their science. The industrial revolution had brought human bodies into constant contact with restless machinery, and the opportunity to help their adaptation had been neglected. Even now some people would take the utmost trouble to care for dead machinery and neglect the care of the human machine. The neglect of science in the great controversy about hours of labour had been pathetic; it had never occurred to either side that shortened hours meant greater output, and that a simple experiment would have shown that both sides could have what they wanted. The demands of war had found no coherent body of knowledge applicable to the problem, but out of the hasty improvisations of that time the Industrial Fatigue Research Board had been born. A most interesting application of physiology had been the astonishing revolution in the health of women with modern dress and habits, so that chlorosis had disappeared. Another great industrialisation of rural populations was taking place—in India and Africa—and this country had a great responsibility to see that this movement was not mismanaged as our own had been—a responsibility that could only be fulfilled in the full light of science.

Nutrition and Diet.

Aggregation in cities had brought about an immense change in the food of the people, and developments in transport and preservation had brought obvious benefits and evils. The chief evil was the dangerous loss of essential food values not to be detected by the ordinary person. The matter was of overwhelming importance and—if choice must be made—should take precedence of housing. The public health officer was empowered to condemn unfit food, but science was calling out for the application of a constructive policy of definite nutritional guidance, for a city physiologist as well as a city bacteriologist. In dietetic improvement lay the hope of remedying the deeply disquieting condition of the national physique, fitness, and beauty, which was the proper test of all public health work. The reduction of infant mortality and the prolongation of life would only lead to a reduced youthful working population supporting a greatly increased elderly population. The country did not need old men, either in war or in peace. The proper test of a country was the number of vigorous young men and women able to do its work. No one could walk through an industrial town or a football crowd without a sinking of the heart, and recent recruiting figures were most ominous. Undoubtedly there were two standards of physique

in the country; the stunted industrial type and the athletic undergraduate type. Neither birth, wealth, nor housing accounted for this difference; as the late Garter King at Arms had said, "the whole of the nation is an aristocracy by blood." The inheritance of the elder son only had prevented any deep social cleavage. Dr. Corry Mann's work, confirmed by others, had shown that this difference in physique was purely a question of food, not of quantity but of quality. The men of bad physique made slums, and any slum clearance that did not improve physique would be expensive, temporary, and palliative.

At the afternoon session Dr. C. HUBERT BOND read a paper on

Local Organisation for the Prevention and Treatment of Mental Disorders.

He set out to show that for many persons suffering from mental illness there was no available treatment, and that for many others available treatment was rendered unsuitable by archaic procedure. He pointed out that of the 20,000 persons who annually came under official cognisance on account of mental disorder a great number had to work out their own salvation, enduring a feeling of inferiority aptly described by the French word *défaillance*. After giving nine examples of cases for which there was at present no treatment available, the speaker emphasised the importance of seizing the "psychological moment," and went on to consider the facilities required for voluntary treatment of incipient mental illness. Undoubtedly, he said, the out-patient department of the general hospital was the best nucleus for a clinic. Patients would go there more readily, and there was every opportunity there for the essential physical investigation. A doctor could probably not do justice to more than five patients in a half-day clinic. The staff of mental hospitals should be large enough for the senior members to spend at least half a day each week in the out-patient department of a general hospital. Beds should be provided for elaborate physical examinations and to remove patients from domestic worries; at present only one general hospital in the country had beds for mental cases. The present state of the law was a serious obstacle to treatment of the incipient case as well as to early treatment of the case for which treatment facilities were available. Dr. Bond gave eight examples where certification was undesirable and unnecessary, and acted as a bar to efficient treatment. These included puerperal insanity, benign stupor after shock, severe delirium tremens, and senile dementia. None of these possessed volition, but none either assented to or refused treatment; all were heedless, indifferent, and free from any grievance at "infringement of liberty." Florence Nightingale had sagely remarked, "It may sound a strange provision to insist, as the first requirement in a hospital, that it should do the sick no harm."

For the mentally disordered patient who was antagonistic to treatment there was adequate provision; they were the smallest group and were by no means irrecoverable. It would be disastrous if the mental hospital became entirely or even mainly concerned with the reception of the "unwilling" patient. There had grown up a very grave abuse of the "urgency" order, so that mental patients were compelled to endure the stress of an interim reception at the poor-law institution instead of being sent straight from their homes.

After outlining and discussing the recommendations of the Royal Commission, 1924, Dr. Bond proposed a scheme of local organisation. Institutions—mental hospitals and colonies for defectives—would be the pivot, belonging to the local authority and governed by "mental health committees," of which there should be one only to deal both with mental defect and mental disorder. The committees should have women members and should arrange for out-patient clinics at the local hospitals and for reciprocity between hospitals, universities, and mental institutions. The chairman and vice-chairman should be

ex-officio members of the public health committee, and there should be members from the public health and education committees on the mental health committee. That committee must have a medical officer—the superintendent of the nearest institution or the lecturer in psychological medicine at the nearest university—and if more than one such authority were available it would be wisest to appoint a special officer distinct from all of them. An important activity would be the medical organisation of school-children from the psychological aspect. The medical staff of the mental institution should have every facility for keeping in touch with the general body of the profession and with recent advances, and the same fluidity of service should be available for mental nurses. Nurses should be allowed periods at convalescent homes, poor-law institutions, or even in private houses. Municipal hospitals might be used as auxiliary units to mental hospitals, or for cases of senile dementia. The general hospital unit should treat neuroses, psychoneuroses, and threatened relapses, and should examine periodically mental defectives, abnormal children and delinquents, and provide a place for interviewing patients absent on trial from mental hospitals. "Boarding out" should be exercised more extensively, and an official should be appointed to do the work now done by the relieving officer in connexion with mental disorder. Health visitors should be of two kinds—those able to supply just the information the staff required about the patient's home, &c., and those who could supply the patient with the information he needed about employment and home conditions when he was discharged, and who were experienced in after-care work. The sympathetic co-operation of the general practitioner was essential to the scheme.

MEDICINE AND THE LAW.

Parent's Refusal to Allow Operation on Child.

FAILURE to provide adequate medical aid is specially mentioned in Section 12 of the Children Act as one of the methods in which a parent may commit the offence of wilfully neglecting a child in a manner likely to cause injury to the child's health. A father was recently charged at Wolverhampton under the section for refusing to permit an operation for enlarged tonsils. The evidence was that the child, a little girl of 6, was at present suffering from deafness and thickened speech, and that her state of health retarded her education. Three school medical officers gave evidence, and the head mistress of the school said that the child was very intelligent, but, because of her state of health, had to be given individual tuition. The father said he was afraid of the possibly fatal results of an operation; he wanted the child to go to an institute where, he said, she could be cured without surgery. He argued that the statutory words, "medical treatment," did not include surgical operations. The justices found the charge proved, but adjourned the case for a month with the intimation that the penalty would depend on the father's action in the meantime.

It is, of course, too late to argue that "medical treatment" in Section 12 excludes surgical operation. In *Oakey v. Jackson* ([1914] 1 K.B. 216) the Melton Mowbray justices, who had thought a father could not be convicted for refusing to permit a surgical operation for the removal of adenoids, were corrected by the judges of the King's Bench Division. Mr. Justice Darling then pointed out that the section mentions "loss of sight" as one of the forms of "injury to health," and that this reference showed clearly that Parliament contemplated cases in which a parent would be bound to allow his child to undergo an operation. In *Jackson's* case the justices, though at first reluctant to convict, did find as a fact that the child was suffering injury to her health from the adenoids, and that the only possible remedy was a surgical operation for their removal. This finding

as all-important. "A refusal to allow an operation," said Darling, J., "is not necessarily such a failure to provide adequate medical aid as to amount to wilful neglect causing injury to health." It is always a question of fact, and the justices have to take into consideration the nature of the operation and the reasonableness of the parent's refusal. One argument for them to consider, added Mr. Justice Story, "is whether the person who advises the operation is a qualified medical practitioner or merely an irresponsible person."

Powders for Cancer.

At an inquest at Exmouth Mr. Tweed, the coroner of the Honiton district, had before him evidence that a man of 75 who had died of cancer had been treated by an unqualified practitioner, Mr. Raphael Roche, of Harley-gardens, Kensington.

"Mr. Roche," said the coroner, "is a well-known man and has been consulted by a great many well-known people; great many tributes have been paid to his skill, and one cannot but think they are genuine. One cannot shut one's eyes to the fact that in many cases cures have been made by persons outside the medical profession; I think it unwise to assume that all treatment outside the profession is to be rejected or regarded as nonsensical. I think Mr. Roche made out a case that he has effected remarkable cures."

The evidence, summarised in the *Times* of Nov. 13th, is as follows. The deceased's daughter said her father consulted Mr. Roche in London last September; her father was charged 15 guineas for the consultation and some medicine. The following day there arrived at Exmouth by post two packets of powder. On Oct. 24th, about four hours after taking the powders, her father became very sick and further doses of medicine were followed by sickness. The analyst's certificate showed that the powders contained no poison: "they consisted of a basis of cane sugar, to which I was unable to find that anything had been added." Mr. Roche said nothing could be found by chemistry or spectrum analysis in any of the drugs he made; he used drugs in an entirely novel way upon which he had offered to lecture to the Medical Council or the College of Physicians, but his offer had not been accepted; his method was to use drugs in non-tangible quantities; the powders contained phosphorus "which could be revealed only by the study of the vital force itself." Before he took patients, he required them to sign a form declaring that they knew him to be an unqualified man, and that no legally qualified doctor whom they had consulted had been able to cure them. Dr. Walker, of Exmouth, who had attended the deceased, said the patient suffered from cancer and could not have lived four or five months. Counsel for Mr. Roche pressed Dr. Walker in cross-examination with regard to his having recommended the analysis of the powders. Dr. Walker drew Mr. Roche's attention to the difficult position of a qualified practitioner who knowingly signs a death certificate where the deceased has been treated by an unqualified man. The coroner recorded a verdict that death was due to a malignant growth in the stomach which caused internal hæmorrhage. Since the inquest interviews with Mr. Roche have appeared in more than one London newspaper. To one interviewer he is reported to have shown—with an unprofessional disregard of the oath of Hippocrates—"a long list of patients, including dukes and earls, and even members of the medical profession." The Honiton coroner is satisfied that he has "effected remarkable cures." It must have been difficult to judge of the nature and success of Mr. Roche's treatment from the evidence in the Exmouth case alone.

RADIUM FOR HOSPITALS.—Westminster Hospital is spending £20,000 upon the purchase of further supplies of radium. The Edmonton Board of Guardians are purchasing half a gramme at a cost of £6000 for use in their North Middlesex Hospital, which is to be constituted a radium centre for the whole of the county of Middlesex.

Rebels and Notices of Books.

PSYCHOLOGICAL CARE OF INFANT AND CHILD.

By Prof. JOHN B. WATSON and ROSALIE WATSON. London: George Allen and Unwin, Ltd. 1928. Pp. 153. 5s.

HAVING won undoubted victories for the behaviourist psychology in the laboratory, Prof. Watson carries the battle into the nursery, and like an invader seeks to impose his order on the conquered territory. Here he has joined hands with Pavlov, whose views must undoubtedly cause a radical change in all future psychological orientation. What Freud has done in the consulting-rooms to unravel or de-condition the minds of his neurotic patients, Watson attempts to do, however, in a prophylactic way in the nursery. That is to say, he seeks to educate parents and nurses in the new objective psychology by showing them that all errors in behaviour are due to the mal-conditioning of a very small number of instinctive-reflex activities. Our behaviour, he holds, is nothing more than the building up of complicated reflex patterns on a few simple inherited themes. By eliminating all extraneous stimuli, by concentrating upon manipulative activities we can turn out useful children socially orderly, clean, and obedient in the best behaviouristic sense. Motherhood, paternity, and nursing thus become scientific crafts with reflex machines to work upon. Knowing what sort of citizens we wish to produce—that is, what behaviour we ask of them—we can produce them almost at will. Thus from the scientific cash register the change will be produced with unfailing fidelity and the reflex child of the future, well-conditioned, will arise to build the new Robot Jerusalem.

It is beyond debate that Prof. Watson deserves credit for introducing scientific methods into psychology and for his application of the neurophysiology of Pavlov to the study of human behaviour. But the fact remains that although much that he says is true, much that he leaves unsaid is equally true. His conception of human psychology has the very limitations which laboratory methods impose, and to suppose that what has been revealed to him in the laboratory is the total of human action is to claim an omnipotence that no scientific method deserves. While the problem of cell life—in metabolism and reacting—still remains a subject for research and discussion, views on human behaviour will have to be debated on a wider field than the behaviouristic. In the behaviourists' world the guiding power bears a striking resemblance to Ivan Petrovitch Pavlov, and the mothers of men are replaced by an iron cow from whose cold udders the child draws his first sustenance. In the real world, however, people will continue to feel that although science will teach them a great deal about their body as an instrument, life itself is too big to be crammed into a reflex machine.

With a consciousness of these limitations we can still recommend this attractively written book. The student of psychology will accept its practical value, and parents will read between the lines, while oblivious of their fate the little Robots play.

THORACIC SURGERY.

Die Chirurgie. Edited by M. KIRSCHNER and O. NORDMANN. Berlin: Urban und Schwarzenberg. Lieferung 18, pp. 273. M.21. Lieferung 20, pp. 189. M.19. (Band IV. Teil 2.)

THESE two volumes are devoted to the thorax, but do not include the surgery of the œsophagus or heart. They contain a series of articles by different authors, profusely illustrated, and give an excellent epitome of the surgery of the air passages, of the pleura, of the lungs, and of the chest wall. The good quality of the work as a whole emphasises certain defects. There are hardly any references to work outside

Germany and Austria; recent instructive work in America, such as that of the Empyema Commission, is ignored. Indeed, in certain articles very little attention is paid to recent work; among the long list of references at the end of the article on pleurisy and empyema, for example, three only are more recent than 1921.

In the first volume the opening chapter, *Die Chirurgie der Lunge*, by A. W. Meyer, deals adequately with the anatomy of the thorax; the physiology and pathology of respiration; differential pressure forms of apparatus with numerous illustrations of the early types of "Ueberdruck-Apparat," and a comparatively brief section on insufflation. At the end only there is a brief account of the principles of technique for pleurotomy, pneumotomy, and for suture of the lung and bronchi. The title of the chapter is therefore somewhat misleading. The next two chapters are on Foreign Bodies in the Bronchi and on "Tracheo-bronchoscopy," by H. Frenzel. These give detailed accounts of the instruments and the methods of using them, and are most complete in this respect. In the former no account is given of the method of extraction of a foreign body if per-bronchial instrumentation fails; nor is reference made to the removal of pus, and to the irrigation of cavities in cases of abscess and bronchiectasis, which Chevalier Jackson, among others, has brought to such a fine art in America. The chapter on Surgery of the Pleura, by Felix Landois, includes injuries to the lungs and pleura. Apart from the omission of traumatic asphyxia, of the important work of the Empyema Commission and of E. A. Graham, and a lack of emphasis on the dangers of early open drainage of pyothorax, the article is good and comprehensive. The final chapter deals with the diaphragm, diaphragmatic hernia, and the phrenic nerve. Herniæ are discussed thoroughly and the various methods of approach and of closure; phrenic evulsion is less completely discussed.

The second volume contains two articles. The first, *Die Chirurgie der Lungen-erkrankungen*, is by W. Jehn. It is clear, concise, and instructive. Space does not permit of details of technique of operations, but the article is well written and well illustrated. In the description of treatment of lung abscess no reference is made to the value of artificial pneumothorax or to thoracoplasty. Again, in the discussion on treatment of bronchiectasis, cautery lobectomy is not mentioned. The second article on *Die Chirurgie des Brustkorbes*, by A. Schubert, is admirable. It must certainly rank as one of the most complete and detailed articles extant on this subject.

DISEASES OF THE SKIN.

Seventh edition. By RICHARD L. SUTTON, M.D., Sc.D., Professor of Dermatology, University of Kansas School of Medicine. In 2 vols. London: Henry Kimpton. 1928. With 1237 illustrations and 11 coloured plates. Pp. 1394. Complete 52s. 6d.

ALTHOUGH approximately 100 pages and illustrations have been added since the sixth edition of this important text-book was reviewed in these columns two years ago, the price remains the same, and we may fairly assume that there will be no diminution in the demand for it. Until a simple and cheap method of colour photography is available, no one could hope to better the illustrations in this work, while the text, the copious and orderly references, brought up to the latter half of 1927, afford a source of information as reliable and succinct as any work on modern dermatology. The author makes constant acknowledgments of the work of his American and European contemporaries.

No branch of the subject is neglected, and the photomicrographs of the various pathological conditions described are admirable. In an age when the clinical manifestations of syphilis are rarely seen in the out-patient departments of our teaching hospitals, the student requires some visual assistance from

illustrations, and even the expert may occasionally require an ocular reminder of type. In this volume there are no less than 12 examples of extragenital chancres alone in the illustrations of the disease, while the clinical photographs from 85 actual cases of syphilodermata and congenital syphilis are supplied, excluding those devoted to the study of the histology. The increasingly important subject of ringworm is also treated exhaustively, both on the clinical and pathological sides. Some 50 illustrations accompany the text, and it is interesting to note that the author for the present, at any rate, expresses himself as being opposed to the recently introduced method of treatment by acetate of thallium for tinea tonsurans.

The rarer diseases, such as yaws, blastomycosis, sporotrichosis, creeping eruption, favus, tinea imbricata, and many others are profusely illustrated. There are few errors or even faults of arrangement or method. One small point that might lead to confusion appears to have escaped the scrutineers of both the sixth and seventh editions. On pp. 1180 and 1267 respectively the treatment of tinea tonsurans and tinea unguium should have received the dignity of separate paragraphs, instead of being allowed to run into each other. There does not appear to be a reference to tinea unguium or even ringworm of the nails in the index. These are almost the only points to criticise in a splendid work which all dermatologists should buy.

RECENT ADVANCES IN PHYSIOLOGY.

Third edition. By C. LOVATT EVANS, D.Sc., F.R.S., Professor of Physiology, University College, London. London: J. and A. Churchill. 1928. With 86 figures. Pp. 403. 12s. 6d.

THREE editions of this excellent book have appeared in three years. While adding two new chapters the author has wisely kept the volume to a handy size by omitting three chapters which appeared in earlier editions on hematology and cardiac output, which subjects are now clearly dealt with in standard textbooks on physiology. The exploitation of physical methods for the study of excitability, chronaxie, and the nature of the nervous impulse is leading to discoveries of fundamental importance; a description of the technique and present position of these studies is presented in the two new chapters in that concise manner which can emanate only from the pen of an experienced worker and teacher. The value of the book is enhanced by the additions, and this edition, too, is likely to be exhausted as rapidly as its predecessors.

HIGH FREQUENCY IN OTO-RHINO-LARYNGOLOGY.

La Haute Fréquence en Oto-Rhino-Laryngologie. Second edition. By LEROUX-ROBERT, Chief of the Physiotherapeutical Branch of the Laryngological Department of the Saint Louis Hospital. Paris: Masson et Cie. Pp. 216. Fr.26.

THIS book on the use of high-frequency currents in diseases of the throat, nose, and ear, was reviewed in our columns¹ on its appearance some three years ago. There is but little alteration in the second edition. One effect obtained by the high-frequency current—namely, diathermo-coagulation, or surgical diathermy—is largely employed by laryngologists in this country. The other forms include diffuse or medical diathermy, "effluve" or "violet ray," and sparking currents or fulguration; these the author uses in a large number of very various conditions, including ozæna, in which he claims to have obtained good results. At the experimental stage, in which this work must still be placed, it would have been helpful if Dr. Leroux-Robert had given a more exact statement of results, and had not been content merely to describe a few selected cases. The applications of surgical diathermy are dismissed with comparative, and rather disappointing, brevity.

¹THE LANCET, 1925, ii., 1287.

PUBLIC HEALTH LABORATORY PRACTICE.

By A. D. STEWART and T. CRAWFORD BOYD.
London: Humphrey Milford, Oxford University Press. 1928. Pp. 306. 12s. 6d.

THIS work is stated to be intended for students taking the D.P.H. examination and for medical officers of health who carry out their own laboratory work. Without restricting the scope of the work, the authors have contrived to produce a book of convenient size by outlining only one method of analysis wherever possible. From the student's point of view this plan has some advantages. The descriptions are explicit and concise and are not interrupted by discursive text-book material—a common fault in laboratory manuals.

The book is evidently not meant for students taking an English qualification in public health. The legal standards for milk, butter, &c., are those of Bengal, although the more important recent English regulations relating to food receive mention. The contrast between Eastern and Western conditions is notably illustrated by the interpretation of results of water analysis. It is surprising to find no reference to plumbo-solvency and plumbo-erosion in connexion with the scheme for detection of poisonous metals in water. From the detail accorded to oils and fats one gathers that the chemical analyses of these substances bulk very largely in Indian public health laboratory practice. It is perhaps also due to this Eastern bias that there is no reference to any method of measuring ultra-violet radiation and atmospheric pollution, problems of increasing importance to modern aggregated communities. Doubtless the manual is well adapted to the needs of students working in the East.

WASSERMANN REACTION.

Die Technik Der Wassermannschen Reaktion und die Technik und praktische Bedeutung der Sachs-Georgi-Reaktion, der Aktivmethode von Bruck, der Ballungsreaktion von R. Müller und der Trübungsreaktionen von Dold und Meinicke. Third edition. By Dr. AUGUST POEHLMANN, a.o. Universitäts-Professor und I. Assistent der Dermatologischen Universitäts-Poliklinik in München. Munich: Rudolph Müller and Steinicke. 1928. Pp. 131. M.6.40.

THIS small volume by Dr. August Poehlmann deals with the technique of performing the Wassermann reaction, includes also sections on the Sachs-Georgi reaction, the Ballungsreaktion of Müller, and the flocculation reactions of Meinicke and Dold. The first part contains a fairly complete summary of the continental literature on the subject of the Wassermann reaction, but the author appears to have ignored practically all the English work; this part of the book is likely to be of greater use to continental workers than to the English reader. This does not apply to the section on the Sachs-Georgi reaction. The subject seldom receives much attention in English text-books, and the description given here, though somewhat brief, is adequate; the same may be said of the flocculation reactions of Meinicke and Dold which appear to have some value though not often employed in this country. The manual should be found useful by laboratory workers.

CHEMISTRY AND MEDICAL PRACTICE.

Recent Advances in Chemistry in Relation to Medical Practice. By W. McKIM MARRIOTT, B.S., M.D., Dean and Professor of Pediatrics, Washington University School of Medicine; Physician-in-Chief, St. Louis Children's Hospital. London: Henry Kimpton. 1928. Pp. 141. 10s. 6d.

THIS volume consists of a series of six lectures delivered at the San Diego Academy of Medicine in 1927. The first deals with the fundamental principles of chemistry, describing the nature of atoms and molecules, and ends with a few paragraphs on osmotic pressure and colloids. Lecture II. is concerned with

acidosis and alkalosis, and the author discusses these conditions from the clinical rather than from the academic point of view, in accordance with the title of the book. Following this lecture is one on the chemistry of the blood, which again provides only a very general outline of the subject, leaving untouched all the technical details usually connected with it. Two lectures are devoted to food and metabolism, the second being concerned chiefly with vitamins and diet. Here as elsewhere the book suffers from lack of references. Often the discoveries discussed in the text do not even bear the original workers' names; for instance, in Lecture V., the fat-soluble A-vitamin is referred to, and we are told of the splitting up of this factor into vitamins A and D—in other words, the separation of the growth-promoting vitamin and the antirachitic factor—but there is no reference at all to the workers who first recognised that these are two fat-soluble vitamins. Again, on p. 111, where reference is made to the exposure of the unsaponifiable fraction of oils to ultra-violet light in order to produce the antirachitic vitamin, no mention is made of the names associated with this work. In the preface the author explains that only general principles are dealt with, since he hopes to rouse the interest of the reader who can then refer to more detailed works on the subject. It is not easy, however, for those without special knowledge to find further information without the clues which the names of the original workers provide. The last lecture of the series, on endocrines, is somewhat superficial, and gives only a very sketchy idea of the history and functions of the various hormones: but here, at least, the names of the pioneers and of some of the principal workers in the field are mentioned, and it would be difficult for the reader to follow up the subject. The lectures deal with a very general aspect of chemistry and summaries of well-known work in a manner well adapted to capture the interest of the general reader. It has the great merit of being accurate in those details which are supplied.

New Inventions.

AN IMPROVED DROP REGULATOR.

IT is perhaps not too much to claim that a drop regulator for controlling the flow of saline and glucose solutions in proctoclysis, and of various antiseptic lotions in the continuous irrigation of septic wounds, is one of the most important pieces of apparatus a ward can possess. I write this note to call attention to the ease with which a dropper can be improvised out of materials readily obtainable anywhere. In essential features the contrivance consists of a small length of glass tubing drawn to a point at one or both ends, some two-thirds of its length being inserted into another small piece of glass tubing of slightly larger diameter. Rubber tubing is then affixed to the ends of the outer piece of glass tubing and a stop-cock regulator attached to the tube on the reservoir side. In practice the apparatus is made up as follows:—

Take the tapering end of a pipette, or an empty ampoule filed off at either end—preferably one thinning out both ways because it is easy to file, such as the saline ampoule of an electrargol set. This is snugly fitted into a short length of glass tubing by means of a thin rubber collar, if necessary, outside the pipette-end or ampoule to make up for any disparity between the outer and inner tubes. All that now remains to be done is to connect rubber tubing to either end of the glass tube and to provide a regulating stop-cock. The same idea may be carried out with an ordinary irrigating nozzle fitted into a filed-off test-tube and connected by a small piece of rubber tube where the base of the nozzle makes contact with the test-tube. There are many other simple variations of these devices which will suggest themselves according to the variety and calibre of the glass tubes available.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 24, 1928.

WHAT IS A GOOD RADIOGRAM?

IN the medical world there is generally a question of the day, when a particular operation or line of treatment or diagnosis is being decried by some and as warmly defended by others. At present radiology is holding the stage. As there is a certain section of the lay public which prefers a medical attendant with alcoholic tendencies on the ground that "he is so clever when sober," so there is in the medical profession a section which blindly follows the result of an X ray examination and believes as it were in a radiogram per se, not knowing whether it is good, bad, or indifferent. This attitude of mind leads to many mistakes and produces much indifferent work. Sir THOMAS HORDER is credited in the lay press with having stated at the Congress on Radiology that the consulting rooms are flooded with bad radiograms. Our own reporter's version of his remarks (see p. 1077), is to the effect that the contribution made by radiology towards the diagnosis of alimentary disease would be even greater than it is if the standard of radiograms were raised. A number of indifferent radiograms might well be exchanged for one or two good ones. The question then arises as to what constitutes a good radiogram. It is easier to say that a bad radiogram is one in which some variation from the normal is not shown owing to want of reasonable care or knowledge on the part of one or other of the persons concerned. But does the onus of a bad radiogram rest entirely on the radiologist? We venture to think not. Other possible culprits, assuming that first-class modern apparatus is used, can only be the patient, and the physician or surgeon at whose request the work is undertaken. The person advising an X ray examination should pass on to the radiologist a tentative diagnosis and such information as will be of use to him in carrying out his part of the work. It is not fair to present the patient to the radiologist in the light of a cross-word puzzle with only the clues present; rather as much as possible should be filled in, and the radiologist asked to complete the missing letters in the light of his special knowledge and opportunities. Opinions differ as to whether a second detailed history should be taken by the radiologist. Some believe that this is desirable on the ground that important points may be elicited which were not mentioned by the patient at the first examination. Such a procedure does not appeal to us. Provided he is furnished with the main facts of the case, as he has a right to be, the time of the radiologist is better employed on his own specialised work. The 15 to 20 minutes so saved may allow of another good look at a doubtful duodenum or an extra film from a different angle. It does not appear right or courteous to send a patient for radiological examination with such captions as "X ray right leg" or "barium meal"; the addition of "Potts fracture" or "suspect duodenal ulcer" at once focuses attention on the immediate problem. The radiologist is a consultant in the light of his specialised knowledge, and it is surely common sense to work up his case for him so that the greatest use may be made of his powers. The preparation of the patient

for special X ray work should be dictated by the radiologist, for his technique is based on a definite preparation and variation from this may lead to error. Lastly, the radiologist must be allowed sufficient time (1) to carry out his examination and (2) to study his plates. Too often he is given 24 or 36 hours in which to administer and report on a barium meal, and is then held up to scorn by a chagrined physician when a ring carcinoma of the sigmoid is found some months later by a complacent surgeon. The radiologist is to blame in allowing himself to be led into such a false position.

The first essential, then, for a good radiogram is full coöperation between physician or surgeon on the one hand and radiologist on the other, before a plate is taken. With the patient the radiologist is bound to exercise his technical skill and his common sense to the utmost. He must be prepared with every legitimate trick of his trade to assist the colleague who has placed a patient in his hands for a special opinion. He cannot afford to confine himself merely to one line of approach, but must be ready to modify his technique as occasion demands. When using only so-called light meals little is learned about the peristalsis of the stomach, while if that organ is only studied fully filled the condition of the mucous membrane cannot be definitely ascertained. In alimentary work a great part of the bowel must be seen in all profiles, for many an ulcer is concealed in the ordinary antero-posterior view. The true character of a gastric papilloma can only be revealed when the patient is studied in various postures. Serial films will demonstrate a rigid piece of bowel and stereoscopic views help to establish the relative position of a shadow. The emptying of a viscus may be more important than the filling, and the completion of an alimentary X ray examination without an opaque enema often leads to disaster. This all takes time, and the radiologist must not be hurried. The man who runs through 20 barium meals in a morning will miss abnormalities picked up by his colleague who refuses to undertake more than four or five. A good radiogram, then, demands from the radiologist the highest technical skill, modified as the occasion demands, and it is generally one of a series, the others being used for purposes of comparison. There remains the most important point, interpretation, to which all the technical work has been preliminary. This again should be done in coöperation. Both sides pool their knowledge and a result so obtained is the one most satisfactory to the third partner—the patient. In work involving hollow viscera, both physician and radiologist should follow their case to operation whenever possible. To be told about it is not sufficient. Experience gained in this way is of the utmost value, for it is then seen what caused the shadow. Dr. BARCLAY told the Congress that if clinical, radiological, and operative diagnoses were compared, it would be found that there was more often agreement between the two latter than the two former.

A good radiogram, then, is one of a series, in the choice of which there has been coöperation beforehand, taken by a radiologist who has exerted his full powers, and interpreted with due regard to previous experience. In the case of a moving viscus it must never be forgotten, as Mr. WALTON remarked at the same discussion, that an X ray film is but a single photograph of a cinematographic performance. Only the watcher of the screen will see the whole plot, and conversely his eye may miss some of the things which the photograph fixes. There is still plenty of room for increased accuracy in diagnosis if radiologist and clinician work hand in hand.

PUBLIC HEALTH LABORATORY PRACTICE.

By A. D. STEWART and T. CRAWFORD BOYD.
London: Humphrey Milford, Oxford University Press. 1928. Pp. 306. 12s. 6d.

THIS work is stated to be intended for students taking the D.P.H. examination and for medical officers of health who carry out their own laboratory work. Without restricting the scope of the work, the authors have contrived to produce a book of convenient size by outlining only one method of analysis wherever possible. From the student's point of view this plan has some advantages. The descriptions are explicit and concise and are not interrupted by discursive text-book material—a common fault in laboratory manuals.

The book is evidently not meant for students taking an English qualification in public health. A good radiogram, then, demands from the radiologist the highest technical skill, modified as the occasion demands, and it is generally one of a series, the others being used for purposes of comparison. There remains the most important point, interpretation, to which all the technical work has been preliminary. This again should be done in coöperation. Both sides pool their knowledge and a result so obtained is the one most satisfactory to the third partner—the patient. In work involving hollow viscera, both physician and radiologist should follow their case to operation whenever possible. To be told about it is not sufficient. Experience gained in this way is of the utmost value, for it is then seen what caused the shadow. Dr. BARCLAY told the Congress that if clinical, radiological, and operative diagnoses were compared, it would be found that there was more often agreement between the two latter than the two former.

A good radiogram, then, is one of a series, in the choice of which there has been coöperation beforehand, taken by a radiologist who has exerted his full powers, and interpreted with due regard to previous experience. In the case of a moving viscus it must never be forgotten, as Mr. WALTON remarked at the same discussion, that an X ray film is but a single photograph of a cinematographic performance. Only the watcher of the screen will see the whole plot, and conversely his eye may miss some of the things which the photograph fixes. There is still plenty of room for increased accuracy in diagnosis if radiologist and clinician work hand in hand.

THE NEXT STAGE.

LAST week we printed a summary of the explanatory memorandum on the provisions of the Local Government Bill and devoted special attention to the proposals for poor-law reform. There remain many other important aspects of the proposed changes which all who are interested in public health will desire to study. It must not be forgotten that the full view of those changes will not be revealed by the text of the Bill alone. The Government has evidently been anxious to leave the initiative in many instances in the hands of the present local authorities, and the "administrative schemes" which those bodies will be expected to submit to the Minister of Health will require close examination. The transferring of hospitals under the Bill raises a point in which the medical profession must take the keenest interest—namely, the imperative need of enlisting and retaining the collaboration of the general practitioner. We have to contemplate that, under the poor-law provisions of the Bill, the county councils will obtain control of almost every public institution in the county area. County councils and county district councils are at present responsible, and will remain responsible, for providing hospitals for infectious diseases. The county council will have to consider which of the existing institutions are suitable for infectious diseases hospitals and how best the existing deficiencies of accommodation can be made good. Clause 11 of the Bill, making consequential amendments of existing law, will give the county council the powers of a local sanitary authority for providing places for the reception of the sick and such provision is to include the conduct of normal labour, which the courts have held not to be included under sickness. The explanatory memorandum adds that Clause 11 also authorises county councils to subscribe to voluntary hospitals, but the Bill is not explicit on this point. The upshot of these arrangements will be that the county council must somehow evolve an orderly system in collaboration with other bodies. It must (under Clause 51) survey the whole accommodation for infectious diseases treatment in the county, put up an adequate scheme for the coördinated use of the hospitals, and arrange for the joint use of institutions owned by single authorities or the provision of additional facilities. If the district councils do not play their part in the scheme, the Minister may transfer their functions to the county councils; if the latter are in default, the Minister may make a scheme himself. All this surveying and unification is admirable enough, but neither the Bill nor the memorandum discloses how the medical personnel of the country is to be applied to the tasks set by the proposed legislative changes. In certain minor ways—for instance, in the insistence on progress towards a system of whole-time public health appointments—the general practitioner may begin to feel that his services and experience will not be welcomed. What steps are being taken to reassure him? We have to remember, of course, that the real campaign for the exposition of the Bill in Parliament and in the country has not yet begun. When the Minister brings to bear upon his immense task his well-known gifts of lucid statement, we shall hope to hear some definite suggestions as to the use to be made of the medical profession.

THE WHITE CELLS IN INFECTION.

THAT infection by the so-called pyogenic organisms is associated with an increase of cells of the neutrophilic granular polymorphonuclear order is so well known that there is a tendency to regard this granular leucocytosis as the only possible response of the white cells to infection. Some of these conditions, however, may produce blood pictures of quite another kind, and two of them, leucopenia and leucocytosis, have special diagnostic importance. The leucopenia of typhoid infection long since found its way into the text-books and lectures, though it is still not fully realised, perhaps, that it is of prime importance in the early diagnosis of enteric fever. The leucopenia of uncomplicated "influenza" is also fairly well recognised, and is one of the grounds for believing that this condition constitutes an entity. So-called catarrhal jaundice, again, is also usually associated with leucopenia.

In the above diseases the decrease of white cells mainly affects the granular leucocytes and thus gives rise to a relative lymphocytosis. In contradistinction to them there are certain other conditions characterised by an actual increase in the number of the mononuclear cells without diminution of the polymorphs; here the picture is one of lymphocytosis without leucopenia. Common, though not very striking, examples of this reaction are seen in measles and mumps, but the most arresting one is found in the condition now commonly known as "infective mononucleosis," whose identity with the "glandular fever" described many years ago by PFEIFFER may be taken as established. In this condition the number of white cells may rise to 20,000 or 30,000 per c.mm., and in extreme cases over 80 per cent. may belong to the mononuclear order. Studies of this disease have lately appeared both in France and America. P. CHEVALIER¹ finds none of the ætiological theories satisfactory, and he concludes that the evidence points to specific infection by an unknown agent. L. D. CADY,² of St. Louis, lays down certain diagnostic criteria, the most important of which, so far as the blood picture is concerned, are the absence of anæmia and the presence of the characteristic mononuclear cells originally described by DOWNEY and MCKINLEY.³ These were placed in three classes, the most numerous and the most important for diagnostic purposes being somewhat larger than normal lymphocytes, with basophile cytoplasm and an eccentric and lobed nucleus. CADY remarks that although usually regarded as a disease of children infective mononucleosis may occur at any age, up to 40 at any rate. J. E. COTTRELL,⁴ writing from Philadelphia, has also observed a series of cases, and draws attention to the necessity of making the differential diagnosis not only from lymphatic leukaemia but also from Vincent's angina with agranulocytosis. In making a decision the recognition of Downey and McKinley's cells is of great importance. The absence of anæmia should exclude leukaemia and severe ulceration of the tonsils, with recovery of the characteristic fusiform bacilli and spirochaetes in smears therefrom, will establish a diagnosis of angina. HERBERT FOX,⁵ also working at Philadelphia, has studied the histology of a tonsil and of a lymph-gland from a case of infective mononucleosis. Both showed hyperplasia of the

¹ Sang, 1928, ii., 166.² Amer. Jour. Med. Sci., 1928, clxxv., 527.³ Downey, H., and McKinley, C. A.: Arch. Int. Med., 1923, xxxii., 82.⁴ Amer. Jour. Med. Sci., 1927, clxxiii., 472.⁵ Ibid.

lymphatic cells, notably of the small ones but also to some extent of the large mononuclears of the germ centres. This worker applied the "supravital" technique of SABIN to the cells from the glands, and satisfied himself that the proliferating cells were actually lymphocytes. Whatever may be the source of the cells giving rise to the increased white count in infective mononucleosis the blood picture produced in man is strongly reminiscent of that seen in infection of rabbits by *Bacillus monocytogenes*, the organism described in 1926 by MURRAY, WEBB, and SWAN.⁶ By the use of the supravital technique WITTS and WEBB⁷ have demonstrated that the increased white cells in this condition actually are monocytes and not of the lymphoid order. Until the same has been done for the peculiar cells of infective mononucleosis their exact nature cannot be regarded as proved. In this connexion it is interesting to note that the avenue of infection by *B. monocytogenes* in the rabbit is the alimentary canal—a route which apparently remains unexplored in connexion with infective mononucleosis in man.

Both leucopenia and lymphocytosis may then represent a response to certain types of infecting agents, of which the bacillus of EBERTH and the unknown organism of infective mononucleosis may be taken as examples. It should be borne in mind, however, that under certain circumstances a leucopenia with a relative lymphocytosis may represent the only response possible on the part of a damaged or abnormal bone-marrow. A number of cases of leucopenia with lymphocytosis in the face of an acute infection involving the bone-marrow were described by S. C. DYKE⁸ in our columns in 1924; and that the peculiar blood picture occurs quite regardless of the nature of the infecting agent was demonstrated by the fact that in three of them the infecting organisms were respectively a streptococcus, the tubercle bacillus, and the colon bacillus. There is some reason to believe that in such cases the bone-marrow is abnormal to start with. Evidence in support of this view is contributed by VLADIMIR JEDLIČKA,⁹ who describes a patient who showed leucopenia or a poor polymorph percentage in the course of several acute infective conditions, finally dying from septicæmia with a white count of 15,000 cells per c.mm., over 80 per cent. of which were myeloblasts; the myeloblastic response in this case obviously represented the death-struggle of a previously aplastic bone marrow. The general conclusion to be reached is that leucopenia or lymphocytosis or both in the course of an acute infection should give rise to consideration whether the peculiarity of the white count is due to the nature of the infecting organism or to some abnormality of the bone marrow. Sometimes the answer to this question may not be easy.

"Ne quid nimis."

ULTRA-VIOLET LIGHT AND CANCER.

THE value of heliotherapy is now well established, and the general public is fully aware of the importance to the ordinary individual of an adequate amount of sunlight throughout the year. But, unfortunately, in this country we have too often to content ourselves with the belief that there is a sun still shining in the sky, ocular proof being denied us. In the quartz mercury-vapour lamp, however, we have an efficient substitute for the sun, or even an improvement on it, for the lamp emits rays which do not appear in the solar spectrum. The lamp is used extensively for therapeutic purposes, and is even employed prophylactically in the domestic bathroom, and except for an occasional burn no one appears to have been any the worse. In a communication appearing in another column, however, Dr. G. M. Findlay brings forward experiments which suggest that ultra-violet light may not always be beneficial in its results. He points out that since 1896 when Unna described under the name "Seemannshaut" the development of cancer of the skin after prolonged exposure to weather, evidence has been steadily accumulating that strong sunlight acting over a period of time may be followed by the growth of carcinoma in the exposed areas of skin. The incidence of this form of cancer is, of course, comparatively small, but there seems no doubt that it actually does occur. With these facts in view Dr. Findlay planned a series of experiments to determine whether ultra-violet light had any carcinogenic action on the skin. A series of mice were tarred on the back in the usual way, after epilation with sodium sulphide, and a certain number of them were also exposed for a brief period four times a week to the rays from a quartz mercury-vapour lamp. It was found that the mice which were exposed to the ultra-violet light developed cancer more rapidly than the controls. In another experiment ten mice were tarred and exposed to the mercury-vapour lamp for one month, ten other control mice being tarred alone for the same period. Both tarring and irradiation were then stopped. At the end of 36 weeks no tumours had developed in the control mice, but three of the irradiated animals had developed cancer, all, in fact, of those who survived, for the mortality among them was high. Finally, 20 mice were epilated and exposed to ultra-violet without being tarred. The mortality in this experiment was again high, but seven of the animals developed innocent or malignant tumours in the exposed area.

Dr. Findlay draws the conclusion that mice exposed to ultra-violet light for a period of not less than eight months develop papillomata or carcinomata. Also, that when a known carcinogenic agent is at work its action is hastened if the animals are also irradiated. And he holds that these experiments support the hypothesis that in man exposure to ultra-violet light plays an important part in the development of cancer of the skin in certain situations. While it is clear that these experiments must be amplified, the conclusions drawn from them appear to be fully justified, and they open up very interesting possibilities. It is true that no case has ever been reported of the development of cancer of the skin after irradiation with ultra-violet light, but it must be remembered that this method of treatment is as yet in its infancy. Various forms of chronic irritation are recognised as causing cancer in man, but except in rare instances they must act over long periods of time. As yet sufficient time has not elapsed for any untoward results of ultra-violet light exposure to declare themselves, if, indeed, they ever will. It is to be hoped they never will, and an alarmist policy is the last thing to be encouraged.

EXTRACTION OF BRONCHIAL MUCUS FOR CONCENTRATION OF BACTERA. The British Anti-Tubercular Association, London, has received from the Hon. Mr. J. H. B. (London) a letter stating that he has been successful in extracting the mucus from the bronchi of a patient suffering from tuberculosis, and has found it to contain a large number of tubercle bacilli. The patient is a man, aged 45, who has been suffering from tuberculosis for some years, and has been treated with various methods, including surgery, but has not been able to get well. He has been advised to try the extraction of mucus, and has done so, with the result that he has been able to get well, and is now able to work and enjoy life. The letter states that the mucus was extracted by means of a special apparatus, and that the patient was able to get well, and is now able to work and enjoy life. The letter also states that the patient has been able to get well, and is now able to work and enjoy life.

Nevertheless, it is well for us to be reminded that light is a very powerful agent which should be used with caution until we are better acquainted with its biological applications.

THE FIFTEENTH SESSION OF THE DENTAL BOARD.

THE autumn session of the Dental Board of the United Kingdom was a short one. In opening it Sir Francis Dyke Acland referred sympathetically to the loss through death of Sir James Hodsdon at the height of his powers, a man whose sagacity and judgment had been at the disposal of the Board and whose wise counsel had been sought in any difficulty. Sir Charles Tomes was one of the Board's trustees at the time of his death, and Sir Francis recalled with gratitude the help received from him in the formidable task of preparing his first address to the Board. He touched on the difficult question of the retention fee, remarking that the Board had fixed a really low payment for practitioners in their early years and thereafter one at which no one ought to grumble. He had come to the conclusion that although financial resources must be carefully husbanded for some years, the Board would not be unduly cramped either in continuing its present work or in starting upon certain new work which was in sight. In a few years the increase of fee income should allow of some expansion. The policy of assisting certain dental schools to provide better teaching, was, he thought, a useful lever for establishing dentistry upon the same plane as any other school of a University or for obtaining the independence due to a particular school. Whilst spending money in this direction the Board had been obliged to be less liberal than heretofore in granting bursaries, and in September last some applicants who might have received grants in previous years were turned down on financial grounds. There had been the usual variety in the type and age of applicants, and whereas in the past bursaries had been awarded to about four-fifths of those eligible for them, the proportion was reduced to about one-half. The progress of the bursars at dental schools continued on the whole to be satisfactory. Turning to disciplinary measures, Sir Francis referred to the new advertising mechanism of daylight signs as applied to dental premises. He proposed that the Board should adhere to the established principle that announcements of practice should be sufficient only to enable persons seeking a practitioner's premises to find them, and he added: "I can think of few cases in which a daylight sign should be necessary for this purpose." Since the last session of the Board the Irish Free State had passed the Dentists Act of 1928, following closely the lines of the Medical Act of 1927, and introducing into dental legislation two important innovations: (1) the obligation on all dentists to pay an annual fee, and (2) the entire prohibition of company practice in the Free State. Finally, he welcomed the probable lightness of their penal duties, a result due, he thought, in part at least, to the strong warning given last session with regard to a certain class of offence.

THE THERMAL STABILITY OF INSULIN.

It is of some importance both to practitioners and pharmacologists to know what sort of variation, if any, may be expected in the activity of medicinal substances when kept for prolonged periods. For this reason an investigation of the Destructive Action of Heat on Insulin, by August Krogh and A. M. Hemmingsen¹ is of special interest. Their actual experiments were made at temperatures from 50° to 117° C., rather above probable storage temperatures. They were all carried out on sterile watery solutions of insulin of about 15 international units per milligramme buffered to pH 3.5 to 4.5, and the activity of the remaining insulin was determined either by the rabbit blood-sugar test of Marks or the mouse

convulsion test described by the authors, which gave satisfactory concordant results. Decomposition was found to follow the course which would be predicted by the law of mass action, and on the whole was comfortably slow. After 623 hours—nearly four weeks—at 50° C., about 60 per cent. of the original activity remained. At the higher temperatures action was naturally much more rapid; in fact, it was found to follow very well Arrhenius's relation between absolute temperature and the velocity constant. The points of chief interest from a medical point of view are that between pH 2 and pH 4 the rate of destruction is not appreciably altered, and that at temperatures likely to occur in ordinary practice the change is very slow, as the following table shows:—

		Time for the activity to fall.		
		5%	10%	50%
40° C.	= 104° F.	1 month	1 month	1 year
30°	= 86°	2 months	4 months	2 years
20°	= 68°	9 "	1½ years	10 "
10°	= 50°	4½ years	8½ "	56 "
0°	= 32°	29 "	58 "	377 "

These times are obtained by extrapolation below the temperatures of experiment and may, in some cases, be in error to the extent of 50 per cent. But they serve to illustrate the satisfactory stability of insulin under ordinary conditions.

LARYNGEAL TUBERCULOSIS.

Of this affection Sir Morell Mackenzie said in 1880 that "the prognosis is always extremely grave, and it is not certain that any cases recover." Since then, however, the outlook has very greatly improved, and it is important that this improvement should be realised, not only by the patients and their friends, but by all practitioners in charge of these cases. A feeling of despair prevents patients from seeking adequate treatment, and persevering in it, whereas the hope of final cure will be found to encourage many to persist in what is often a lengthy and tedious régime. That some degree of hopefulness is justifiable is shown by the experience of Dr. E. A. Looper and Dr. L. V. Schneider with 500 cases at the Maryland State Sanatorium in the past six years.¹ Of these cases 142 were classed as having "moderate lung involvement," and 358 "advanced lung involvement"; in the first group 108 patients, or 76 per cent., were "improved and healed," and of the second group 109, or 30 per cent. It is well known that the prognosis of laryngeal tuberculosis depends very largely upon the extent and the progressive character of the pulmonary disease; the class of case admissible at different hospitals and sanatoriums also varies greatly. Looper and Schneider do not define what is meant by moderate or advanced lung involvement, and do not seem to have adopted a definite method of classification, such as the Turban-Gerhardt. In these circumstances statistics have only a relative value, and, judging by the discussion that followed a reading of the paper at the Minneapolis congress, the percentage of cures is higher than that obtained by other laryngologists in America. In this country Sir StClair Thomson² reported 25 per cent. of cures at the King Edward Sanatorium at Midhurst, and Mr. Harold Barwell³ about 21 per cent. at Mount Vernon Hospital, where cases admitted in an advanced stage for the relief of dysphagia were excluded from the statistics. Both these authorities agree with Looper and Schneider in insisting on the importance of periodic examination of the larynx in all cases of phthisis. The methods of treatment advocated are also those most generally accepted in this country and may be summed up as general sanatorium regimen, silence, and galvano-cautery puncture. Contra-indications to the last method of treatment are high temperature, marked asthenia, and high blood pressure; the American writers enunciate a sound

¹ Jour. Amer. Med. Assoc., Oct. 6th, p. 1012.

² THE LANCET, 1924, ii., 948.

³ Diseases of the Larynx. London, 1928.

¹ Biochem. Jour., 1928, xxii., 1231.

principle, that no laryngologist should undertake electro-cautery treatment without the coöperation of a clinician, and they add that indiscriminate use of the cautery in unsuitable cases will do more harm than good, and the method of treatment itself will thus be brought into disrepute. They give figures to show the beneficial results of treatment by the cautery. In the group of moderate involvement of the lung 65.5 per cent. had the larynx cauterised and were healed and 10.6 per cent. were healed without cauterisation; but many of the latter class were patients with more active disease whose general condition did not allow of this method of treatment. Statistical comparisons of this kind are thus obviously open to fallacy, but there is no doubt that galvanocautery puncture is a valuable method of treatment in carefully selected cases. It is interesting to observe that experience in the United States agrees so closely with that in England. Looper and Schneider have done good service in bringing this method to the notice of their colleagues, for they rightly remark that it is surprising that this form of treatment is not more generally employed.

TRAUMATIC RETINAL ANGIOPATHY.

A VERY rare condition of the fundus, ascribed to a contusion of the skull, was described at the Heidelberg Ophthalmological Congress of 1910 under the title *Angiopathia Retinae Traumatica* by Purtscher, of Klagenfurt. It was due, he suggested, to an effusion of lymph into the retina following a sudden rise of pressure in the cranium, a direct connexion being assumed to exist between the cerebro-spinal fluid and the perilymphatics of the retinal veins. A few similar cases have since been observed, and C. H. Chow, of Peking, adds another in the November number of the *British Journal of Ophthalmology*. It was the result of a blow with a cricket ball on the orbit and right side of the face. A week after the accident there was a patch of opacity along the course of the upper temporal vessels extending from the disc about 5 or 6 disc-diameters. There was considerable disturbance of pigment and an absolute scotoma corresponding to the lesion. Five weeks later there was extensive migration of the pigment from the outer retinal layers to the inner, where it was seen in the form of minute black dots apparently outside the sheaths of the retinal vessels. The author finds that in his case the pigment was non-hæmorrhagic and non-inflammatory, and that it was derived from the pigmented epithelial layer of the retina. The scotoma remained unchanged. A somewhat similar case has recently been reported with photographs of the fundus in the *Archives of Ophthalmology* by A. J. Bedell, of Albany, New York. No reference is given to any similar case reported in Great Britain.

THE INHERITANCE OF MIGRAINE.

ALTHOUGH not in itself a serious complaint, migraine in the aggregate ranks high as a cause of suffering and invalidity in the general population. It forms a readily recognisable symptom-group, and though its ætiology and mechanism of production is unknown, and treatment, prophylactic or curative, at the best unsatisfactory, there are certain features closely associated with it. Of these, a history of similar attacks in parents or other members of the family has been the subject of attention from time to time since as far back as the beginning of the eighteenth century. During that period the reported proportion of cases of migraine in which a parental history is obtainable has gradually risen until at the present time the view is held that in almost all instances a hereditary tendency is manifest. In a recent paper,¹ read at a joint session of Eugenics Societies in New York, Dr. William Allan has dealt with this aspect of the subject. He defines migraine as "any headache beginning in early life, recur-

ring regularly or irregularly over a long period of years, without discoverable pathological process and without materially affecting the general state of health," and he then proceeds to associate his observations on the familial occurrence of the complaint with the laws of heredity originally propounded by Mendel. The few previous attempts of this nature have led to contradictory findings as to the dominance or recessiveness of the trait. This is not surprising, for where the character (migraine) is a subjective phenomenon not capable of mechanical measurements, and its allelomorph is not a definite character, but simply absence of headache, the usual criteria of dominance and recessiveness are impracticable. The observed figures can only be compared with the expected results, the character being first considered as a dominant and then as a recessive. In dealing with any hereditary trait, it is necessary to know the relative frequency of the factors concerned, and from these can be calculated the relative occurrence of homozygous dominants, heterozygous dominants, and recessives. A positive history of migraine in a sample of 282 men was obtained by Dr. Allan in 57.4 per cent., whereas in 384 females the incidence was 62.6 per cent. Using these results it is possible to construct tables showing the results to be expected in mass matings of various types. On the basis of a general adult population incidence of 60 per cent. Dr. Allan has constructed two such tables considering migraine first as a dominant and then as a recessive character, and with these he has compared the actual findings in his series of 500 cases. The genetic and statistical evidence presented by the author is in close accord with the results to be expected if migraine be regarded as a dominant unit Mendelian character. A possible source of error, however, lies in the figures collected for the incidence of migraine in the general adult population, from which the samples were taken. A percentage of over 50 seems surprisingly high, and it is a debatable point whether the definition of migraine which formed the basis of the investigation was not too broad.

CONTROL OF MALARIA IN CENTRAL AMERICA.

IN presenting his sixteenth annual report¹ to the United Fruit Company which has immense activities in the development of Central America, Dr. W. E. Deeks, general manager of the medical department, admits that malaria is still their major problem. Dr. Deeks has himself contributed in no small measure, both by his own work and by the stimulating efforts of example, to the solution of the control and cure of the disease which stands across the progress of the company's work. In the present report the papers by Dr. O. T. Brosius, Dr. M. A. Barber, Dr. W. H. W. Komp, and Dr. N. P. McPhail on the special properties of quinine and plasmoquine in malaria are the most searching that have yet appeared, based as they are on a vast clinical material. As a result of these studies, Dr. Deeks sets out his conclusions as follows: (1) Quinine is specific against the schizonts of all kinds of malaria and these are responsible for the clinical symptoms. In acute cases it is still the drug of election, but in order to obtain prompt results, large doses (2-3 g. daily) must be given. (2) In acute cases the exhibition of quinine for short periods favours the appearance of gametocytes in the peripheral blood, either by driving the gametocytes from the deep viscera, or by creating an environment which causes the development of increased numbers of gametocytes. When developed under quinine administration gametocytes are viable. (3) Plasmoquine is mainly effective against gametocytes, but it has also a marked action in clearing the schizonts of the tertian and quartan types of malaria from the peripheral blood, while upon the schizonts of the subtertian type its action is negligible and apparently, as in Brosius's report, it does not prevent the development of blackwater fever. Moreover, it is not as

¹ *Archives of Internal Medicine*, 1928, xlii., 590.

¹ United Fruit Company, Medical Department, 17, Battery-place, New York. 1927. Pp. 365.

effective in preventing relapses when administered alone as it is in combination with quinine. (4) Plasmoquine has a toxic action on crescents of subtertian malaria, and after a few doses mosquitoes feeding on infected individuals do not become infected. The use of plasmoquine thus, if this observation is confirmed, will be of great importance in malaria control. (5) If given in too large a dosage, or over too prolonged a period, plasmoquine may cause toxic symptoms. In a small percentage of cases there may be, as with quinine, an idiosyncrasy to the drug. The daily dosage should not exceed 0.06 g., and this should not be continued over a period exceeding six days unless the patient is under close observation. (6) The toxic symptoms are headache, giddiness, gastric distress, and cyanosis, and the drug may cause death. At the onset of toxic symptoms there is a leucocytosis and degeneration of the erythrocytes. (7) The administration of quinine in combination with plasmoquine apparently prevents the development of toxic symptoms and, because of this, and the therapeutic action of the two drugs on different phases of the parasite, they should always be given in combination in order to get the best clinical results. (8) Experience shows that for an adult the amount of quinine to be given daily in combination with plasmoquine depends upon the clinical symptoms. In chronic cases 1 g. daily will suffice; in acute cases 2-3 g. daily are necessary in order to obtain optimal results. (9) In ambulatory cases the daily dosage of plasmoquine should not exceed 0.04 g. in combination with 1-2 g. of quinine for a period not exceeding six days. Whenever possible all cases so treated should return for re-examination within three to four days after the course is completed.

HUMIDITY AND TUBERCLE.

THE high relative humidity which preceded the violent storms of last week had the usual depressing effect on those who cannot readily get rid of their superfluous heat. It seems that there are many people whose dermal organ is trained to react only to a small range of atmospheric conditions and who are easily upset by a dry wind or by moist stillness. While the devastating effect of these extremes is no doubt largely confined to those whose mechanism of heat balance is inefficient, a certain amount of evidence has accumulated as to the effect of rain-bearing winds on the health of the general population. In his last annual report to the Derbyshire Health Committee, of which a summary, in other respects is given in another column, Dr. W. M. Ash records the results of an investigation into the influence of such winds upon cases of early phthisis in that county. The material analysed is a series of 306 first-stage cases which had been treated at the county sanatorium and followed up at their homes for four years after discharge. Dr. Ash comes to the conclusion that in Derbyshire, as Dr. W. Gordon found in Devonshire, and others have found in West Shropshire and elsewhere, there is evidence that patients with early phthisis die more often and recover more rarely when residing in exposure to strong prevalent rain-bearing winds than when residing in shelter from them. If these observations are of wide application they have their obvious bearing on the choice of sites for sanatoriums and for the residence of the individual tuberculous patient. Exact proof of this thesis is beset with a multitude of difficulties, suspected and unsuspected by those who have worked on the subject. The equation can hardly be solved where there are so many unknowns. A small but useful contribution, however, comes from the School of Hygiene and Public Health at the Johns Hopkins University, Baltimore, where two observers¹ have analysed the effect of high humidity and moderately high temperature on the susceptibility and resistance to tuberculosis in guinea-pigs. The result was in effect negative, for under the conditions of the

experiment they found that the susceptibility and resistance of guinea-pigs to infection with a virulent strain of tubercle bacillus was no different at a temperature of 80° F. with 79 per cent. relative humidity, and a temperature of 69° F. with 45 per cent. relative humidity. These observers rightly remark that what is true of the guinea-pig is not necessarily true for other animals and human beings, especially in this case as the guinea-pig is originally a tropical animal; but the value of work of this kind is that it can be carried out under accurately controlled conditions, in which there are fewer unknown factors in the equation to be solved.

THE APPRAISAL FORM.

AN account¹ has reached us from America of a method of stimulating different forms of public health work which appears to have been used in some 200 cities during the past three years. It consists of a voluntary periodical stocktaking based not on the local need for civil health work, nor on the results of such work, nor even (except indirectly) on its quality, but on the amount of activity shown by the various local health agencies, official or voluntary. From a simple score card for dairies introduced in 1903 by the Health Officer of the District of Columbia and taken up by the Department of Agriculture, the idea of assessing health activity in this way developed in the United States through a series of more or less independent local schemes, some of which failed to fulfil any serious purpose through faulty methods of drawing up their schedules. The latest and most widely adopted form results from the joint efforts of the Committee on Administrative Practice of the American Public Health Association and of the American Child Health Association. It is issued by the former under the title of "Appraisal Form for City Health Work." The form is described as a document of 68 pages and the essential part of it—i.e., the scoring device—is divided into 11 sections, each section representing one of the common chief public health activities in cities. These are: vital statistics, communicable disease control, venereal disease control, tuberculosis control, prenatal hygiene, infant hygiene, pre-school hygiene, school-child hygiene, sanitation, including food, milk, water, and sewer control, laboratory service, and popular health instruction. Each of these is divided again into a number of "criteria," 131 in all, each with a numerical score attached to it. For instance, under communicable diseases come "nurses' visits per case diphtheria," and so forth; under tuberculosis, "clinic visits per 100 deaths," "cases reported per annual death"; under sanitation, "dwellings with sewer connexion per cent.," "milk pasteurised per cent.," and so on. An arbitrary standard of score was fixed, being based on the score reached by 25 per cent. of a group of cities in a preliminary trial. The assumption is obviously made, under several headings, that in no city all the cases needing treatment are reached; otherwise it is hard to see why it should count to a city's credit to have a high percentage of, e.g., tonsil and adenoid operations, or of heart and lung defects placed under a physician's care, or of glasses fitted or teeth extracted, all reckoned on the total number of school-children rather than on the relative need of the individual. One wonders, too, whether—even in American cities—the social class of the people concerned would not affect such scores as the percentage of nurses' visits or clinic visits in prenatal, infant, or pre-school welfare work, the percentage here again being reckoned on the total live births or pre-school population respectively. These and other points are, however, under consideration, and the need for changing standards and criteria is recognised. Industrial health measures and those for which the need is confined to special areas, such as malaria

¹ Anna M. Baetjer and Linda B. Lange: *Amer. Jour. of Hyg.*, 1928, viii., 935.

¹ The Validity of the Appraisal Form as a Measure of Administrative Health Practice. By Philip S. Platt. Published by the American Public Health Association.

and hookworm control, are not as yet included. We note, too, that the preventive work done by the practitioner which so often goes unrecognised but is probably more effective than all the other measures, is so far completely left out of account, owing to the difficulty of getting any sort of records.

Among the uses claimed for this appraisal form are the auditing of a city's health resources and the provision of a definite goal, the measurement of progress year by year, the stimulation of individual health workers, and the encouragement of health agencies to keep better records. Moreover, it is naively suggested that it may serve to defend the record of a health officer on objective unbiased grounds when he is threatened with a political attack or removal. The total score obtained by a city is looked on as of minor importance compared to the value attaching to a methodical periodical self-analysis. The form is specially aimed at measuring the means to an end and not the results reached. Even if not misused, and no suggestion of unwise use of it has come to knowledge, it is not clear to us why the means should be preferred to the end as an object of measurement. Mr. Platt gives an analysis of the results obtained in applying the appraisal form to a group of 46 cities in 1926, referring also to a somewhat similar earlier trial on a group of 86 cities in 1923, and discusses in detail whether this form really measures what it sets out to measure, and the sort of revision that should be made. When the 46 cities are divided into groups according to their populations—these varied from 15,000 to 1,250,000, half being under 50,000—there is little difference between the high scores reached in each group, but much between the low ones; the lowest, as might be expected, are in the smaller cities. It would have been of some interest if the relation of total score to population had been given in more detail, since the figures suggest that up to a point (but not beyond it) health service provision increases with population; but it is unsafe to draw conclusions, for the 46 cities are by no means a random sample of American cities. The labour of making such a survey is not small. Mr. Platt estimates that the time for an individual to appraise a small or moderately sized city is one to two weeks, but in large or specially difficult cities it may take several months to finish the work, which involves scores of interviews and, where records are badly kept, much tabulation of raw data. It is debatable whether such labour is really spent to the best advantage, and whether the end in view would not be better served by the type of district survey provided by Mr. Mess's recent book, "Industrial Tyneside," lately reviewed in our columns,* rather than by this numerical marking system. The Tyneside method, though admittedly more laborious, incidentally fulfils all the aims of the appraisal form as well as providing an end-product full of interest and value instead of a numerical score. We doubt whether this particular method will be popular outside those communities which rely on local boosting and stunts such as "Better Cities Contests" to maintain the civic pride of their inhabitants.

Lady Osler, whose many bequests for the benefit of medical education are noted in another column (p. 1109), has left her house at Norham-gardens, Oxford, to the Dean and Chapter of Christ Church, to be assigned as an official residence for the Regius Professor of Medicine in the University of Oxford for the time being, or otherwise applied towards the endowment of that chair.

THE official report of the International Conference on Cancer held in London last July has now been issued as an imposing volume of nearly 600 pages. Some of the communications delivered at the conference have already been published in full in our columns or elsewhere, and, where this is so, only an

abstract is printed in the report, which contains no illustrations other than charts. Its appearance will be welcomed by the delegates who had to choose which sections to attend, and even more by those unable to come to the conference at all. All the aspects of cancer were discussed from different points of view, and this record of the proceedings confirms the impression that the British Empire Cancer Campaign did a service to medical research in collecting a group of experts and inducing them to explain their experiences and exchange their views.

On Saturday last Lord Mildmay of Flete, as Lord Lieutenant of Devon, opened the new Torbay Hospital which has been built to the design of Mr. H. Percy Adams. Founded in 1850, the original building has long been inadequate to the needs of Torquay, whose population has greatly increased of late years. As the site did not permit of expansion, Hengrave House and its grounds were purchased in 1924 from Mr. and Mrs. R. P. Kitson, who later added 7 or 8 acres as a gift. The donation of £100,000, since considerably augmented, by Mrs. Rowcroft, has made it possible to build on this site a modern hospital, including a children's ward, private wards, two operating theatres, and a maternity ward. Accommodation for out-patients is ample, and there is apparatus for electrotherapy and radiological work, including a supply of radium. An antenatal centre is to be added. By adaptation and additional building Hengrave House has been transformed into a nurses' home.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. E. L. Atkinson is placed on the Retd. List with the rank of Surg. Capt.

Surg. Comdrs.: J. H. B. Martin to *Egmont*, for R.N. Hospl., Malta; and J. D. Murphy to *President*, for three weeks' course at R.A.F. Medical Officers' School of Instruction. Surg. Lt.-Comdr. H. Hurst to *Pembroke*, for Chatham Dockyard.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt. (D) W. M. Bull to be Surg. Lt.-Comdr. (D).
Surg. Sub-Lt. A. R. Thomas to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Cpts. to be Majs.: E. F. W. Mackenzie, R. D. Davy, F. A. L'Estrange, and W. M. Cameron.
Capt. A. G. Harsant to be Maj. (Prov.).
Capt. G. Fleming is re-empld. under Art. 507 (b), Royal Warrant for Pay and Promotion, 1926.
J. A. Timoney and W. G. Harvey to be Lts. on prob.
C. P. Allen to be Temp. Lt.

TERRITORIAL ARMY.

Lt. R. W. Power to be Capt.

RESERVE OF AIR FORCE OFFICERS.

Flight Lt. J. W. Harper is transferred from Class Dii. to Class Di.

Flight Lt. Dumaresq Le Bas relinquishes his commission on completion of service, and is permitted to retain his rank.

INDIAN MEDICAL SERVICE.

Capt. Jagat Ram Kochhar to be Maj.
Lt. J. C. Lamont resigns his commn.
Temp. Capt. A. N. Duggal relinquishes his temp. commn.

CHRISTMAS MEDICAL TOUR IN THE FRENCH RIVIERA.—As already announced a medical tour is being organised by the Société Médicale du Littoral Méditerranéen from Dec. 27th to Jan. 7th. The itinerary includes a visit to Hyères, St. Raphael-Valescure, Cannes, Grasse, Nice, Beaulieu, Monaco, Monte Carlo, and Mentone. Particulars can be obtained from Mme. Juppé-Blaise, Federation of the Health Resorts of France, 1, Gordon-square, London, W.C. 1.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XII.—TESTS OF RENAL EFFICIENCY.

By G. A. HARRISON, M.D.,

CHEMICAL PATHOLOGIST TO ST. BARTHOLOMEW'S HOSPITAL.

I.*—GENERAL CONSIDERATIONS: UREA-CONCENTRATION TEST.

RENAL function tests, like other laboratory tests, must be regarded as an extension of the clinical examination. If the urine is free from protein, investigations of kidney efficiency are unnecessary. Theoretically, it is possible that gross kidney damage could be followed by complete scarring, and so the renal function might be deficient in the absence of proteinuria. In practice this state of affairs is so rare that it may be regarded as virtually non-existent. Proteinuria having been detected, an examination of the centrifuged urinary deposit should invariably be made. If there are no cells, no casts, and nothing abnormal in the deposit, the proteinuria may be of no significance (intermittent proteinuria). If the deposit is abnormal, the kidneys should not be regarded as healthy unless subsequent careful and repeated observations have justified such a conclusion.

Tests of renal efficiency are relatively gross; they give results which do not differ from the normal until the damage is extensive, and involves some two-thirds to three-quarters of the total renal tissue. The finding of proteinuria and an abnormal deposit but "normal" renal function tests therefore indicates that renal damage lies somewhere between the zero and the two-thirds or three-quarter stage. Other essential points are: 1. Conclusions drawn from renal efficiency tests only apply on the day of the test; the investigations must be repeated at intervals as guides to prognosis or to treatment. 2. The efficiency tests may give a rough measure of the degree of damage; they give no indication of the cause or type of damage, whether nephritis, tumour, stone, or other lesion. 3. When interpreting reports, the possible influence of non-renal factors—e.g., a failing circulation—should always be considered.

The kidneys have three main functions: (a) excretory; (b) regulation of osmotic pressure of the blood; and (c) regulation of acid-base balance of the blood. Of these three the first is most readily tested, the last two being often influenced also by non-renal factors and requiring relatively more elaborate technique. Many methods have been devised to test the excretory function, but it is only necessary here to mention a few of the simplest and most widely used—viz., the urea-concentration test, blood analysis, and the dye tests.

UREA-CONCENTRATION TEST.

The object of this test, devised by MacLean and de Wesselow, is to force the kidneys to concentrate urea by flooding the blood with urea, and by withholding fluids for 8 to 12 hours beforehand.

Technique.

Performance of test in ward or patient's home. Nothing to drink overnight—e.g., nothing after 10 P.M. Next morning, at

5.58 A.M.: Empty the bladder completely. Label specimen "0."

6 A.M.: Drink the dose of urea.

7 A.M.: Empty the bladder again. Specimen "1."

8 A.M.: Pass urine again. Specimen "2."

9 A.M.: Pass urine once more. Specimen "3."

Place each specimen in a separate bottle and label each. The whole of the urine passed in specimens 1, 2, and 3 should be sent. A sample of specimen "0" will suffice.

* Part II. will appear next week.

Breakfast may be taken before or during the test, if desired, so long as it is a "dry" breakfast. No tea, coffee, milk, &c., is allowed. The test may be started at 6.30 A.M. or 7 A.M., or at any other convenient time in the early morning, so long as complete samples of urine are obtained at hourly intervals as in the above example, and so long as all fluids are withheld previously for 8 to 12 hours.

Urea prescription for an adult is:—

R. Urea	..	..	..	15 g.
Tincture of orange	..	..	..	1 c.cm.
Water, to	..	..	..	100 c.cm.

The following dose of urea for children has been found satisfactory in practice.

Age in years.	G. of urea.	C.cm. of above prescription.
12 and over	.. 15	.. 100
8 to 12	.. 12	.. 80
5 to 8	.. 10 (approx.)	.. 70
3 to 5	.. 7½	.. 50
1 to 3	.. 6	.. 40
Under 1	.. 4 (approx.)	.. 25

Laboratory Determinations.—Measure the volume of urine in c.cm. and estimate the percentage of urea in each of specimens 1, 2, and 3. The volumes are measured in order to detect excessive diuresis. The hypobromite method for the estimation of urea is sufficiently accurate for clinical purposes, in that only relatively gross variations in urea concentration have any significance.

Interpretation of Results.

(a) *Volume of Urine.*—If the concentration of urea is subnormal, the first thing to exclude is excessive diuresis. The volume of urine should not exceed 120 c.cm. (4 oz.) in the first hour or 100 c.cm. (3½ oz.) in the second and each subsequent hour. If the volumes do exceed these amounts, a low concentration is *not necessarily* indicative of deficient renal function, and it is advisable to repeat the test. Excessive diuresis is most commonly due to imperfect preparation for the test. Occasionally, in spite of withholding fluids for 8 to 12 hours previously, there may be excessive diuresis owing to release of water previously retained in the tissues. It is merely a matter of convenience whether the test be repeated on the same or on another day, there being no objection to giving a second dose of urea two or three hours after the first. If the urea concentration be good in spite of excessive diuresis there is obviously no need to repeat the test.

(b) *Concentration of Urea.*—The information required is the maximum concentration of urea. It does not matter whether this occurs in the first, second, or third hour. Usually the maximum is found in the second or third, but occasionally in the first hour. Normally, the maximum concentration exceeds 2.5 per cent., frequently being greater than 3 per cent. Figures between 2.5 and 2.0 per cent. may be regarded as within the boundary zone. Their significance should be carefully assessed in the light of all the evidence available, and if any doubt remains as to the efficiency of the kidneys further tests should be performed—e.g., an estimation of the blood urea. Figures below 2 per cent. generally indicate renal inadequacy, always assuming that the test has been properly executed.

Value of the Test.

On account of its simplicity the test has been used extensively in all branches of urinary disease. It is very useful in clinical work, and undoubtedly will reveal the presence of a serious degree of renal inefficiency in the vast majority of cases. There are, however, a few conditions in which it is apt to be misleading at first sight. Thus, in the purely hydræmic type of nephritis with chloride retention, but no nitrogenous retention, it gives normal results, and yet the patient may be at death's door. Again, in some cases of enlarged prostate the urea-concentration test has been normal before operation, and yet the patient has died from septicæmia or toxæmia 24 or 48 hours after prostatectomy. The test is a measure of the efficiency of nitrogenous excretion,

and of that only. We have no right, therefore, to expect it to give warning of septic complications.

The urea-concentration test is a provocative test. That is to say, by flooding the blood with urea an attempt is made to provoke the kidneys to excrete urea at higher concentrations than on an ordinary diet. It is possible that in a damaged kidney such provocation makes a call upon some of its "reserve." Possibly for this reason the urea-concentration test is more sensitive than many others, such as the blood-urea test. But that it is a comparatively gross test was shown by a case in which the urea concentration was perfectly normal, although one of the kidneys had been removed following a street accident. It would appear, therefore, that more than half the renal tissue may be functionless, and yet this test will yield "normal" results.

Special Articles.

THE UNIVERSITY OF LONDON: THE NEW STATUTES.

By PERCY M. WALLACE, M.A. OXF.

II.

THOSE readers of THE LANCET whose attention I may have had the good fortune to retain throughout the perusal of my three preceding articles (of September 24th and October 1st, 1927, and last week) will not have failed to perceive that the duties imposed on the Commissioners of 1898 and 1926 respectively differed very considerably. In the former case it was as though a sturdy youth, having skipped the difficult period of adolescence and attained manhood at one stride, had to be forthwith furnished with an entirely new suit. In the latter the man, twenty-eight years older, had justified his earlier sudden transformation, and was on the whole well content with his equipment, but his friends had observed that in some respects he moved constrainedly and was unable to do himself full justice; his suit must therefore be let out here and the linings strengthened there, and he must be further supplied with an additional cardigan for the better protection of his chest.¹ In less frivolous language, whereas the earlier Commissioners had to design a constitution and government almost from a new beginning, the later, working upon the organisation established by their predecessors, were called upon to enlarge its scope, to ease its methods, to re-dispose its material, and to re-adjust its machinery, with a special eye to the improvement of its financial administration.

My task in the present article will therefore be to indicate directly, with such comments as may appear helpful, those amendments of the constitution of 1900 which, in general conformity with the instructions of the Act of 1926, the Commissioners have embodied in the Statutes which they sealed on July 23rd, and which will come into operation as soon as they have been approved by the Privy Council.

They commence by declaring the "purposes" of the University to be "to hold forth to all classes and denominations, both in the United Kingdom and elsewhere, without any distinction whatsoever, an encouragement for pursuing a regular and liberal course of education; to promote research and the advancement of science and learning; and to organise, improve and extend education of a University standard." This definition is repeated from that provided by the Statutes of 1900, except that the final clause formerly ran:—"to organise, improve and extend higher education within the appointed radius." The amended phrase recognises that not all "higher education" falls within the province of a University;

¹ The paronomasia was not intentional, and I hope I shall be pardoned for letting it stand—an unconscious but not unhappy echo of the picturesque archaic terminology of my own University.

and by the omission of the concluding four words effect is given to the opinion of the Departmental Committee of 1924 that no area need be statutorily defined. As I indicated in my article of September 24th, 1927, there are at present three areas for different purposes of the University—two precise and one vague; this is a cumbrous complication, and the University may well be trusted to handle with common sense any matters upon which the question of area or distance may arise.

His Majesty in Council remains the Visitor, and the Chancellor, appointed by Convocation, the "Head" of the University. The Vice-Chancellor will continue to be elected yearly by the Senate, but this body will no longer be limited to election from within its own membership. The removal of this restriction was specifically recommended by the Departmental Committee on the ground that there might be occasions when no member of the Senate was peculiarly qualified to hold the post, or, being so qualified, was able or willing to devote the time necessary for the effective discharge of its duties. It is this extension of eligibility, we may presume, which has made compulsory—what has hitherto been only permissive—the annual appointment of a member of the Senate to act for the Vice-Chancellor in case of his temporary illness or absence.

The Principalship is also for the first time made a statutory office. Under the moribund constitution the Senate were empowered to appoint a "Principal Officer," not necessarily one of themselves, "to assist in the general government of the University," with "such title, powers, duties and salary" as they might determine; alternatively, they might assign such powers, duties, and salary to the Vice-Chancellor. From the very first it was obvious that in so huge and complicated an organisation no man could adequately perform at the same time the presidential and ceremonial duties and those attached to the control of a numerous administrative and financial staff. At the earliest possible moment after the reconstitution of 1900 a Principal was appointed as a whole-time salaried official, and, except for the period 1915-20, when owing to the stringency of War conditions the office was put into commission, this arrangement has continued down to the present time. From the year 1920 onwards the formal title of the incumbent has been "Principal Officer"; this awkward and occasionally ridiculous anomaly has now been swept away without remark, and the old designation, as known to other British Universities, receives authoritative re-establishment. The Principal is to be the "chief administrative officer of the University," responsible, under the decisions of the Court and the Senate, for the organisation and conduct of its financial and administrative business. He will be an *ex officio* member of the Senate and of all its Standing Committees, but is debarred from membership of the Court and of the governing body of any School. It will be his "right and duty" to advise the Court and the Senate on all matters affecting the policy, finance, government and administration of the University, with unrestricted rights of attendance and speech at Meetings of all bodies, executive or advisory, charged with the consideration of these matters, and authority over the staffs assigned to them. The present Principal Officer is to be the first holder of this reconstituted and enlarged office, with a salary at least equal to that attached to his original appointment.

So much for the chief officials. We now come to the bodies to which will be entrusted the government and administration of the great machine.

I referred just now to the "Court." This term, however, does not designate a body similar to those that generally bear the title in modern English Universities. As I stated last week, the Departmental Committee of 1924 pronounced definitely against the proposal made by the Haldane Commission that there should be a large body, of "about 200" members, in supreme control, specially charged with ceremonial and legislative functions. It is to the small body

concerned solely with finance, for which the Committee suggested the title of "Council," that the Commissioners have transferred the more exceptional designation of "Court."² This body is to consist of 16 persons—the Chancellor, the Vice-Chancellor, the Chairman of Convocation, six persons appointed by the Senate from their own number, four appointed by His Majesty in Council,³ two by the London County Council,³ and one co-opted by the other 15 members. Appointments will normally (*i.e.*, as soon as the Court has got definitely into its stride after the necessarily shorter tenure of most of the original members) be for five years. The Court will elect its own Chairman. It is to have "the custody, control and disposition of all the property, funds and investments" of the University, with full authority in respect of leases, loans, and contracts. It will be in control of all financial matters, with "power to determine finally any question of finance arising out of the administration of the University or the execution of its policy," subject to the proviso that, before determining any question of finance which directly affects educational policy, it must take into consideration the views of the Senate thereon. It is to be responsible for all measures "necessary or desirable for the conservation or augmentation of the resources" of the University, and is to check action or liability accordingly. It is to represent the University in all negotiations for grants from public bodies, and without its consent no School (except in the Faculty of Theology) is to be permitted to receive such grants, make public appeals for money, or accept benefactions which might in its opinion become onerous. It is to "determine the allocation of all funds at the disposal of the University," with the stipulation that, in respect of the Senate's own "central activities" (under suitable heads and sub-heads) and the expenditure by Schools "as part of their general income," recurrent grants are normally to be allocated in the form of block grants; and is also to appropriate at its discretion funds for the maintenance of the property of the University and of an adequate staff for its financial and administrative business. To enable it to carry out these duties fully and effectively, the Court is to be entitled to ask for any information it considers necessary from any body or official in the University and from the authorities of any School, and to prescribe the manner, form, and periodicity of all Accounts and Estimates.

The considerations which led the Departmental Committee to recommend the entrustment of financial supremacy to this new body were indicated last week, together with arguments that have been put forward in opposition. It only remains, in summarising more precisely the terms of reference to the Court embodied in the new Statutes, to repeat the confident expectation that, in spite of the unreasonableness urged by its opponents, the scheme will not creak unduly in the working, still less give birth, through lack of intelligent sympathy and good will on both sides, to a succession of embittered dead-

locks. It may be presumed that in practice the procedure will be analogous to that which has for many years been observed under the obsolescent constitution—that no recommendation involving fresh expenditure will be submitted to the Senate by any Committee until it has received the approval of the Court, or, as may occasionally be found necessary, that any such resolution of the Senate will be specifically subject to such approval.

The Senate, though deprived of the ultimate control of finance, will remain the "supreme governing and executive body of the University in all academic matters," and except for that limitation (which, as has been suggested, may prove to be more in seeming than in substance) are charged to "take such measures and act in such manner as shall appear to them best calculated to promote the interests of the University as a place of education, learning and research." The constitution of this body is to differ in several respects from that prescribed for it in 1900. The Chancellor, Vice-Chancellor, and Chairman of Convocation remain, and, as already indicated, the Principal is to be added as a fourth *ex officio* member. Next in order are placed "the Heads [these generally bear the title of Principal] . . . of the following Schools"⁴:—University College, King's College, Bedford College, Birkbeck College, East London College, the Imperial College of Science and Technology, the London School of Economics, the Royal Holloway College, and Westfield College, provision being made, in the event of any of these ceasing to be a School, for the substitution of another School should the Senate consider this course desirable. Under a special separate clause, the two first-named Colleges are—in recognition, presumably, of their longer history and more comprehensive purview—to retain their exceptional representation on the Senate. In addition to their respective Heads, there is to be a member appointed direct by the University College Committee and one by the Council of King's College. It is to be observed, however, that the latter is the governing body not of the College as the term is generally understood (*viz.*, the original foundation without its Theological and its Advanced Medical Departments), but of its Theological Department, which, as has been already explained, stands now on its own feet as a School of the University in the Faculty of Theology, and has since the administration of the other Departments of the College was taken over by the University enjoyed the right of appointing a member of the Senate. The two prerogative institutions are thus to retain in a re-adjusted and not logically defensible scheme the special representation granted them by the Statutes of 1900, University College henceforth sending its Provost and an appointee of its Committee, and King's College its (secular) Principal and an appointee of its (theological) Council. Then come 17 representatives of Convocation; of these there are on the present Senate 16, the difference being due to the diminution by one of the graduates in Science and the addition of one each of those in Engineering and Economics—two categories that did

² No explanation is given of this alteration in nomenclature, but it is not difficult to conjecture to what considerations it was due. As will be made plain in the following paragraphs, the Court will stand *sui generis*, controlling finance, and in all this province supreme. The Senate will be supreme in all academic matters, and will be advised by five Standing Committees, each known as a Council. Behind these will be the Faculties and Boards of Faculties, and behind them the Boards of Studies. Each rank in the hierarchy will thus have a distinct generic title of its own. The convenience derived from this obviation of natural misunderstandings in an intricate organism will be, in actual practice, very great. In the constitution of 1900 the University Extension Board stood correlative with the Academic Council and the External Council, but its title sometimes obscured this status through a mis-association with that of the Boards of Studies. A suggestion was recently made to re-name the two Councils the Academic "Board" and the External "Board" respectively; this would certainly have effected the due ordinance of the three chief Committees, and left the field clear for the Council (*tout court*) as the financial authority; but increased confusion with the Boards of Studies would have been in daily commerce an incessant source of irritation—far more serious than would be easily comprehended by those who have not been constantly concerned with the operation of so delicate a mechanism.

³ The Treasury and the London County Council are the two largest channels of public financial support for the University.

⁴ Constitutional purism may properly demur to the comprehension of University College and King's College in this category, as also to the special extension of the term "governing body" to include the University College Committee and the King's College Delegacy. Upon incorporation in the University both these Colleges surrendered their independent existence and autonomy, and came under the control and administration of the Senate, the immediate supervision of the work of each being, as I explained before, entrusted to one of its Committees acting on the spot. But the Commissioners were in this regard bound by the specific declaration in the Act by which they were appointed that the term "governing body" was applicable to these two Committees; after that it would have been almost an affectation to refuse to the two Colleges the title of "School." From the point of view of practical convenience there can be no doubt that their inclusion in the terminology applied to the normal Schools is, however irregular constitutionally, an innovation of manifest advantage.—It may be noted, that survival of the former indication of their peculiar status, that these two institutions are still officially designated "University of London, University College" and "University of London, King's College" respectively, in contradistinction to the style "Guy's Hospital Medical School (University of London)," "Westfield College (University of London)," formally prescribed for the normal Schools in the several Faculties.

not exist at the date of the promulgation of the Statutes of 1900. The number of Faculty members, otherwise remaining unaltered, is also increased to 17 by the allocation of an additional representative to the Faculty of Engineering—in recognition, no doubt, of the development of its work during the past twenty-eight years and its obvious division into the two branches of Civil and Mechanical Engineering and Electrical Engineering.

Such of my readers as have not already learnt the facts from another source will at this stage have observed with dismay that no Medical School appears in the foregoing list of the Schools that are to be represented on the Senate by their respective Heads. This category is confined (except in the case of Westfield College) to such Schools as have been admitted in two or more Faculties, and have thus a larger institutional stake in the University than the one-Faculty Schools in Theology and Medicine. But these two classes are manifestly not on a level in being so described. Theology may fairly be regarded as one subject. But the organisation and control of medical education occupies so prominent a position in the history and structure of the University, and is concerned with so varied and extensive a *clientele*, that the Commissioners have specially allotted to the General Medical Schools,* acting in common, two representatives on the Senate, to be elected from among themselves by their own Deans (or other "chief executive officers"); moreover, in the event of one of the first-named nine Schools falling out and no other School being substituted for it, the Senate are specifically empowered at their discretion to fill the vacancy so caused by increasing this joint representation of the General Medical Schools from two to three. This representation is, of course, in addition to the three Faculty members who are continued from the scheme now on the eve of supersession. Thus on the new Senate there will be two representatives of the graduates in Medicine, three of the Faculty of Medicine, and two (possibly three) of the General Medical Schools which are for the time being Schools of the University. The membership is to be completed by the co-optation by the rest of four (in certain circumstances five) more persons, not necessarily members of the University.

Such are the retentions on and additions to the Senate. The bodies which lose representation are the Crown, the Royal Colleges of Physicians and Surgeons, the four Inns of Court, the Law Society, the Corporation of the City of London, the London County Council, and the City and Guilds of London Institute. With regard to these it may be remarked that the four Crown members and the two County Council representatives will now have their place on the Court; the co-operation of the Royal Colleges, each of which sent two members, and of the Corporation and the City and Guilds Institute, each of which sent one, highly valuable as it was in 1900, is not essential now that the University has "found itself" and can walk alone: and the disappearance of the Inns of Court and the Law Society seems a natural consequence of the failure of the legal profession to co-operate with the Senate in the establishment of a great School of Law within the University, as mentioned by me in September, 1927. On the general question it may be presumed that the Commissioners have acted upon the opinion expressed by the Departmental Committee that there is "no justification for the system whereby so many Senators are nominated by bodies none of which has an organic connexion with the University and most of which have no similar privileges in other universities." The total membership of the Senate will thus be 54 (or 55 if the Vice-Chancellor is elected from outside); this is a larger number than that recommended by the Departmental Committee, who had urged a reduction from the existing 56 to 49; but the Commissioners

have been led to prescribe the increase by their conviction of the urgent desirability of providing for ample representation, not only of the graduates and the teaching staff, but also of the chief administrative units within the University. Apart from the 13 who occupy their seats by virtue of their positions, members will normally hold office for four years.

The Senate will be "supreme . . . in all academic matters," and is authorised to delegate any of its powers to any Standing or other Committee, with or without power to such Committee to sub-delegate such powers to any subordinate Committee. It may be presumed that, until it has thought out a coherent scheme of delegation, it will continue the present practice of receiving Reports from its Committees and adopting definite resolutions after consideration of the reasoned advice thus put before it.

There are to be five Standing Committees, the membership of each of which is in greater or less degree governed by Statute, the completion lying in the hands of the Senate, who are not confined in their appointments to members of their own body.

Priority of place is, as hitherto, accorded to the Academic Council, which will consist of the Vice-Chancellor, the Principal, the 17 Faculty members, and nine other persons appointed annually by the Senate, who in making these appointments are to have regard, *inter alia*, to "subjects of study and academic interests not otherwise represented" on the Council, and to take into consideration any views laid before them by any Board of Faculty, Board of Studies, or other analogous body. This Council is to advise the Senate, and where authorised to take executive action, in respect of the various matters that fell within the purview of its predecessor—the admission of Schools; the establishment, duties, and remuneration of Professorships, Readerships, and Lecturerships "of the University"; the recognition of Teachers; degrees, curricula, and examinations for Internal Students, and academic work generally. It will also be concerned with the constitution and personnel of Faculties, Boards of Faculties, and Boards of Studies, and with the regulation and co-ordination of their work.

The External Council is to consist of the Vice-Chancellor, the Principal, the 17 Convocation members, and nine other persons, in whose appointment the Senate are to have regard, *inter alia*, to "the adequate representation on the Council of the views of public educational institutions at which substantial numbers of students follow courses of study for the External degrees of the University"; this novel feature should prove most beneficial if it keeps the Senate in touch with the conditions and experience of the provincial Colleges and other institutions "not carried on for private gain or profit" which are vitally concerned with the special problems of this department of their work. To this Council the Senate will similarly look for advice and action regarding External Students—their degrees, diplomas, syllabuses, facilities for study, guidance, and examinations.

We then come to the second of the main innovations introduced by the Commissioners in pursuance of the general policy of the Departmental Committee—the Collegiate Council. This body is to consist of the Vice-Chancellor, the Principal, the eleven (or more) Heads or chief executive officers of Schools who have seats on the Senate, together with "so many additional members as the Senate may from time to time determine to represent Schools or groups of Schools not already represented on the Council, such additional members to be, in the case of a single School, the Head of that School, and in the case of a group of Schools the Head of one of the Schools in the group to be elected by the Governing Bodies of the Schools in the group acting through their Heads." The chief duty laid upon this Council is to advise the Senate upon what the Departmental Committee described as "institutional and inter-institutional matters." The primary items of this category, as set out in the new Statutes, are the

* These are still, as in 1900, twelve in number, and need no specification in these columns. (For other—i.e., non-General—Schools in the Faculty of Medicine see footnote below.)

"appropriate and adequate share" to be taken by each School in the teaching work of the University and the most advantageous distribution among the institutions of teachers, equipment, and facilities for teaching and research; and special stress is laid upon co-operation for the provision of common courses of instruction, common examinations, and common facilities for original study and research and the interchange of teachers and students, and upon the organisation and extension of favourable conditions for social intercourse and recreation and the maintenance of "a high standard of conduct" among students. These objects are plainly of paramount importance if the University is to become in the amplest sense of the term an organic unity, having its work co-ordinated for the general advantage and its various resources conveniently, effectively, and economically utilised. There has hitherto been no statutory provision for the representation on the Senate or any other central body of any School other than University and King's Colleges, and even these have not necessarily been represented by their administrative Heads. Some other Heads of Schools and Institutions have from time to time been appointed to the Senate by the Crown or by one of the Faculties or by Convocation. But this indirect and accidental method is not adequate. Still less is the requirement met by the only occasions for conference among members of the several Schools actually provided by the existing Statutes—the meetings of Teachers on Boards of Studies and Faculties, for these are concerned only with such details as lie within the narrow limits of isolated subjects or hardly less isolated groups of cognate subjects. Such opportunities as Heads of Schools have hitherto enjoyed for the comprehensive and responsible discussion of the larger aspects of organisation and co-operation just enumerated have been those occasionally afforded by their own voluntary and uncorrelated efforts. Much therefore may be expected from this statutory recognition of a grave deficiency and provision for its redress. One example of what can be achieved in this direction is supplied by the partial adoption, to which I referred in my article of October 1st, 1927, of the scheme recommended by the Statutes of 1900 for the concentration of preliminary and intermediate medical studies.

Of the other two Standing Committees instituted by the new Statutes, the University Extension and Tutorial Classes Council and the Matriculation and School Examinations Council, it would not be relevant to say more in these columns than that they are charged, under re-adjusted organisation, with the supervision of those branches of the work of the University which are indicated by their respective titles—the former with what is known in another place as "extra-mural" study, the latter with the various avenues of entry to the University and the inspection and examination of secondary schools.

In addition to these five Committees of prerogative rank, the Senate will have power to constitute others at its discretion. Of this nature there were during last Session (excluding the Finance Committee and others whose work will now be otherwise provided for) no less than 25, dealing with such special subjects as the Goldsmiths' College, the Institute of Historical Research, the Diploma for Journalism, the Library, Military Commissions, Scholarships, Establishment and General Purposes, and so forth.

The eight Faculties remain as hitherto, except that it is definitely provided that every fully recognised Teacher shall henceforth be assigned to one or more, though (as at present) no person will be entitled to vote in more than one at Senatorial elections. They will continue to be available for consultation by the Senate or any of its Committees upon any matter at their discretion, but without any compulsion so to consult; and they will retain their present right to report of their own motion upon a number of subjects in which they are respectively interested. That this right has under the obsolescent Statutes been comparatively rarely exercised has been in some cases

due to their cumbrous dimensions. For this special defect a remedy is now provided. The voluntary and tentative institution by the Senate a few years ago of Faculty Boards is now to be formally incorporated in the fabric of the University. The Senate are directed to appoint a Board of Faculty (as the title will run henceforth) for each of the Faculties of Arts, Medicine, and Science by name, and normally ("unless for special reasons they otherwise determine") for any other Faculty in which there are more than one Board of Studies; there may even be one appointed for any Faculty in which there is only one. It is not easy to predict with confidence the exact effects of an instruction so confusedly permissive; but, as the assignment of Boards of Studies to Faculties now stands, we may reasonably expect that in the near future only two (at most three) Faculties will remain without a Board of Faculty—those of Laws and Music (and possibly Theology), for, if variety of subject is to be taken as the criterion, it is not clear on what principle either Engineering or Economics should be excepted from the normally compulsory clause. It may be remembered that last October I mentioned that the Faculty Boards had been in some quarters regarded as an unnecessary complication of the academic machinery; now that they are to be invested with statutory authority and definite functions, they will of course enjoy an enhanced prestige. The business of each will be to advise the Academic and External Councils upon a number of matters within the purview of its Faculty—the scope and correlation of courses of study and examinations, the provision for teaching and research, the conditions of graduation and the award of certificates and diplomas, the *personnel* of Boards of Studies, and any other matters that may be referred to it. Each will consist of the Dean of the Faculty, all members of the Senate who are "members of or graduates in the Faculty,"⁶ one representative (when the Senate think it desirable, two or more) of each of the comprised Boards of Studies, and not more than five other members of the Faculty to be appointed by the Senate on the nomination of that body.

In view of the range and importance of those matters in which the Academic Council at least will require the frequent assistance of these Boards of Faculties, and of the exceptional unwieldiness for regular consultation of the Faculty of Medicine with its present membership of over 400, it may be profitable at this point to consider how under the new regime the constitution of the Board of this Faculty will actually work out. The Dean and five to eight Senators will have seats *ex officio*. At the time of writing (and there is no reason to anticipate any noteworthy alteration in this matter) there are nine Boards of Studies within the Faculty—those of Preliminary Medical Studies, Intermediate Medical Studies, Advanced Medical Studies, Dentistry, Pharmacy, Hygiene and Public Health, Physiology, Human Anatomy and Morphology, and Pharmacology; in view of the comprehensive character of some of these, it may be presumed that the members under this category may number from 14 to 16. Then there will be from seven to nine of the members of the Senate (duplication will plainly be avoidable in normal cases); and there may (probably will) be five others. This gives a total membership of about 35—a number large enough to include for most purposes all specialised interests even in a Faculty

⁶ In this phrase we find statutory warrant for that ambiguous signification of the word "Faculty" which has occasionally given rise in the terminology of the University to a considerable degree of misapprehension—not to say exasperation. Its primary, and according to the framers of the Statutes of 1900 its only strict, usage during the last twenty-eight years has been to designate corporately those individually selected Teachers who have been admitted by the Senate to membership of one or more of the eight electoral and in a limited degree of advisory bodies bearing that title, as indicated above. In this Statute the term is also used—so conveniently as to be almost inevitably—to signify that department of undergraduate or post-graduate study within the University which in the case of successful students leads to a distinctive degree. There are of course other meanings of the word in other Universities—and in popular phraseology.

of such wide content, and yet not too large to preclude the probability of the regular attendance of a predominant proportion of the same persons—a most desirable feature in a body of this function. In this respect Medicine will share with Engineering (with four Boards of Studies) and Economics (with nine) a favourable position between Arts and Science (with 21 each) on the one hand and Theology (with three) and Laws and Music (with one each) on the other—for it is not only in the domain of logic that intension varies inversely with extension. If, as seems beyond question, these Boards of Faculties become a vital element in the academic structure, it is probable that, while such bodies as the Committee of the Medical Members of the Senate (to which the Departmental Committee referred slightly as redundant, ill-conceived, and possibly unconstitutional) will cease to exist, the Faculties themselves will, save on exceptional occasions, be more and more limited in actual practice to their original function of periodically electing to the Senate the representatives of the teaching staff of the University.

The province of the Boards of Studies (at the present time 45 in number) remains generally the same as hitherto, except that the wording of the obsolescent Statutes specifically forbidding the Academic Council or the External Council to advise the Senate upon "any matter relating to courses of study, provision for teaching or research, examinations and the appointment of Examiners, or the granting of degrees or certificates of proficiency" without first taking the opinion thereon of the relevant Boards has been modified both in absoluteness of tone and in scope of application. But this does not really indicate any sacrifice of safeguards—it is merely a recognition that the Senate can be trusted in the matter of common sense. The normal procedure under the old dispensation will not be materially affected in any sense adverse to the dignity or authority of the Boards; they will continue to be consulted on all technical points, but there will no longer be the tiresome delays that have from time to time held up urgent business until some Board should have reported on some detail of procedure. On the other hand they may in future be called upon, within their respective spheres, to advise not only these two Councils but also any other Committee of the Senate (Standing or otherwise) or Board of Faculty, or even the Senate itself direct. The number of the Boards, which are to be appointed annually, is left to the discretion of the Senate; probably there will be no great change in the present Register. With regard to personnel, it is now specifically prescribed that, where practicable, each Board must include all the Appointed Teachers of its own subject or subjects and some of those of cognate subjects, also Recognised Teachers of and "other persons": expert in such subjects or cognate subjects—the number in these two categories taken together not to exceed that of the Appointed Teachers.

The conditions that will govern the examinations for and the conferment of the several degrees are set forth in terms that, generally speaking, incorporate in the existing code such adjustments as the accumulated experience of the last twenty-eight years has shown to be expedient. These do not require detailed analysis here, and it will be sufficient to mention, for such readers of THE LANCET as may not be aware of the fact, that, although it is under present conditions incredible that the Senate should ever desire to confer (as they technically may) the degree of Doctor of Philosophy in the Faculty of Medicine, they have added two to the traditional four (M.B., B.S., M.D., and M.S.) to which in that Faculty they were limited by the Statutes of 1900—those of Bachelor of Dental

Surgery and Bachelor of Pharmacy, for the institution of which the approval of His Majesty in Council was obtained in 1921 and 1925 respectively.

Similarly, and finally, those of the new Statutes that deal specifically with the Schools of the University and its Teachers (Appointed and Recognised) do little more than consolidate the Statutes of 1900, as interpreted and expanded since that date by amendments designed to meet successive needs. Two points may, however, be noted as of characteristic interest. The first is the formal adoption of the system of Boards of Advisors as an integral feature of the process of "appointing" Teachers or of conferring the status or title of Professor or Reader—a merited tribute to the marked success that has crowned this device, of which I gave some account last October. The second must afford even livelier satisfaction to those who have striven and are striving to get the best possible work out of the machine entrusted to their hands. Among the further conditions upon which henceforth the Senate must statutorily satisfy themselves before admitting any institution to the grade of School^s are the willingness of its governing body to leave in the hands of the University the conferment of the status or title of Professor or Reader upon members of the staff and to observe its requirements with regard to appointments to the higher teaching posts, the extent to which the teaching staff may take part in its management, and the adequacy of the provision made for recreation and corporate and social life. The relations of the University with its several Schools, and with the members of the staffs appointed by them both prior to the reconstitution of 1900 and since that date, have been of necessity so delicate, and grave divergences of view might so easily have arisen in regard to rights and privileges, that what we may take to be this agreed stabilisation on more intimate lines of a system honourable and profitable to all parties must be regarded as of most hopeful augury. It is, indeed, manifest that without such mutual confidence and genuine co-operation between the University and its Schools the experiment inaugurated twenty-eight years ago must have failed to realise the aspirations of those who devised it. That this central feature of the organisation should have proved susceptible of harmonious and equitable operation must be most gratifying and encouraging to all who wish well to the University.

For fuller details of the revised constitution those interested will consult the Statutes themselves. My part in this and the three preceding articles has been to indicate in outline, with illustrations mainly drawn from the medical department, how prolonged and how devoted have been the efforts of some of the keenest and most expert authorities in the country to solve a long-standing problem—*quantac molis* has been the endeavour to equip the capital of the Empire with a University worthy of her exceptional wealth in academic material and potentialities.⁹

⁹ In addition to the twelve "General Medical Schools" (and University College and King's College in respect of preliminary and intermediate medical studies), the following are at the present time Schools of the University in the Faculty of Medicine (in some cases only for certain subjects or for limited periods):—the London School of Hygiene and Tropical Medicine, the Lister Institute of Preventive Medicine, the Royal Army Medical College, the Royal Dental Hospital and School of Dental Surgery, the Naval Medical School of the Royal Naval College (Greenwich), the Maudsley Hospital, Bethlem Royal Hospital, the School of Pharmacy, and the Cancer Hospital. There are a number of other Institutions at which there are Recognised Teachers in subjects comprised within the Faculty.

⁹ In view of the special character of the *clientèle* of THE LANCET, I trust I may be allowed, in a final footnote, to call attention to a remarkable fact in connection with the tenure of the Vice-Chancellorship during the past twenty-seven years—that is, since the Senate were first able to exercise their free right of election (the first Vice-Chancellor under the existing Statutes having been appointed by the Statutes themselves). Election to this office has been annual, and the Senate have been obliged to elect one of their own body. Although the direct representation of Medicine on the Senate has been only nine out of a total membership (excluding the Chancellor) of fifty-five, the choice has fallen upon a Physician or a Surgeon on seventeen occasions out of the twenty-seven. From 1911 to 1924 the medical profession had an unbroken run.

⁹ It may be presumed, though it is not precisely stated, that this phrase does not include members of staffs of Schools or Institutions that have not obtained recognition as Teachers, but designates experts who, having no such association with the University, are able and willing to assist its work by accepting appointment to its Boards of Studies.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Instruction in Sexual Physiology.

THE Edinburgh education authority has come to certain provisional and rather hesitating findings on instruction of children about the physiology of reproduction. The essential findings of the authority are:

(a) That a special meeting (or meetings) should be held once a year of parents of children above 12 years of age, other than those attending the transferred Roman Catholic schools.

(b) That a short list of pamphlets be drawn up and approved for the use of headmasters, teachers, and parents. Such pamphlets to be available for sale at the meetings, but not to be issued to the children.

(c) That should any parents express a desire for such instruction to be given to their children, it should be done only by such members of the teaching staff as are willing to do so, and in the opinion of the headmaster qualified, or by one of the medical staff—the instruction to be given in all cases by a person of the same sex as the child. No class instruction shall be given.

Prof. J. Y. Simpson, a member of the authority and himself a distinguished teacher of biology, suggested that biology should be taught in secondary schools, and in relation to (c) entered a caveat against the policy of limiting the kind of instruction and the types of person that should convey it. The decision of competence to teach in this field ought not to lie with the headmaster. The special committee concerned, it appears, considered "that the responsibility of imparting information as to the origin of life lies with the parents," and this is approved by the Committee on Religious Instruction. "At the moment it does not seem likely," the special committee continues, "that the primary schools will ever provide direct instruction in sex hygiene—at any rate, it cannot be given until public opinion recognises sufficiently the necessity for such instruction and exhibits confidence in the ability of responsible advisors of children to give the instruction needed." The committees display no sign of the suspicion that the vast majority of parents are too ignorant of sex hygiene to undertake, with safety, this work, even if there were not between father and son, or between mother and daughter, that well-known barrier of reticent delicacy in all matters of sex.

Pensions for Nurses.

In connexion with the Federated Superannuation Scheme for Nurses and Hospital Officers, a meeting of representatives of voluntary hospitals in Scotland was lately held at Glasgow. It was pointed out that a nurse, while she was working, had very little opportunity of saving anything, and there was an obligation on the community, who owed so much to her, to see that when the time came for her to cease working there should be some provision which would help her to live in comfort. The Federated Superannuation Scheme was a contributory scheme. It was national in its character, and had been framed to meet the needs of all hospitals, irrespective of their size. It was framed on the general lines of the federated superannuation system for universities. This scheme had the advantage that under it a nurse had the option when the retiring age came of receiving either a lump sum or an annuity for the remainder of her life. Moreover, if she so desired it, the benefit could take the form of an endowment insurance. The scheme was worked by means of assurance policies issued to each individual by well-known life assurance associations, so that there could be no doubt of its solvency at any time. One of the principal objects of the scheme was to provide that when members moved from one hospital to another they should carry their policies with them.

The Universities.

Prof. F. G. Banting, of London, Ontario, delivered on Oct. 31st his Cameron Prize lecture to a large audience of students and medical graduates at

Edinburgh. Prof. Banting, who was awarded the Cameron Prize of 1927, told the story of his researches in detail and recounted the various experiments which led up to the discovery of insulin.

Mr. Thomas William Drinkwater, Ph.D., was recently entertained at dinner by the Royal College of Surgeons of Edinburgh, in honour of having completed 50 years as a lecturer in the School of Medicine of the Royal Colleges of Physicians and Surgeons. Sir David Wallace, presiding over a company including some 40 fellow lecturers and colleagues in the School of Medicine, said it was a unique event that a lecturer should have continued to hold classes for so long a period. After completing his medical studies at St. Thomas's Hospital, London, and at Edinburgh, Dr. Drinkwater qualified as L.R.C.P. in 1878 and almost immediately took up lecturing on chemistry. Besides conducting large classes, he was one of the earliest chemists to do analytical work in connexion with the public health movement, and he is still actively engaged in teaching and in chemical analysis for medico-legal work. He is a Fellow of the Royal Society of Edinburgh and of the Institute of Chemistry.

It is stated that of the 3978 students from outside the British Isles at British universities, Edinburgh has the highest number, 574, Cambridge being second with 546, Oxford third with 507, University College, London, fourth with 312, and Glasgow University fifth with 190.

The Problem of the Feeble-minded.

Dr. R. D. Clarkson, of the Royal Scottish National Institution, Larbert, lecturing to the City of Glasgow Society of Social Service on Nov. 9th, pointed out that mental deficiency was extremely difficult to define and the definitions in the Mental Deficiency Act were not helpful. The highest grade defined in the Act was that of the feeble-minded who were said to require supervision and control for their own protection, or the protection of others. In the case of children, the feeble-minded were those who were incapable of obtaining proper benefit from the ordinary instruction in elementary schools. It was agreed that about 1 per cent. of the children in the schools did not derive benefit, and on this basis it would seem that there should be about 50,000 in Scotland; but the number known to the General Board of Control was only about 3000. It was practically certain, however, that incapacity at school did not necessarily mean incapacity to earn a living in later life. Mental deficiency might arise—e.g., from disease or injury—in any family, and no distinct line could be drawn between the mental defective and the normal member of the community. It was probable that heredity did not account for a very large proportion of defectives. There was far too little institutional accommodation for defectives in Scotland, said Dr. Clarkson. Of the 3000 known to the General Board of Control about 1800 were in institutions, and of these only 634 were in institutions for adults. Experience at Larbert seemed to show that every training school for defectives should have an industrial colony in connexion with it under the same management, because defectives transplanted badly.

Dental Benefit.

In the third of a series of popular health talks at the Edinburgh Y.M.C.A. hall, Mr. Douglas Radford gave an excellent summary of our knowledge of diseased teeth. He pointed out that nearly every disease is influenced by the mouth being in a condition of suppuration, and often the degree of oral cleanliness decides whether the end of a serious illness is death or recovery. Such teaching should help to awaken interest in the maintenance of dental benefit under the National Health Insurance. At present it is, of course, only an additional benefit, though the dental profession put forward a strong case before the Royal Commission for making it statutory. This was not accepted and the large dental service, involving some £3,000,000 in England and £250,000 in Scotland, with

its Advisory Committee and inspecting and consulting officers, depends entirely on the allocated part of the surplus funds emerging at the last valuation of the approved societies. The allocation covers only five years, and at the end of this period the societies and central authorities will be faced with the alternatives of finding money to continue the service or of dropping it; for it is much less likely than it was that the next valuation will show a surplus equal to the last, if it shows any at all. The last reorganisation of responsibilities put more on the approved societies and less on the State grant. Hence these tears. It is time the profession were taking steps to preserve a service so well begun and recognised on all hands as one of the best developments tried under the Insurance Acts. It is monstrous to think that a service so far-reaching in its effects should be allowed to drop or to diminish merely because the so-called "surplus" may not emerge. Experience has proved that dental benefit and ophthalmic benefit are in very widespread demand, and it will be very poor statesmanship that fails to keep these services in being.

A Point of Law.

A curious point in procedure has arisen in the Lanarkshire Sheriff Court. The county council raised a case in its capacity as executive local authority under the Diseases of Animals Acts, the complaint being dismissed by the Sheriff on the ground that the Procurator-General alone had the right to institute proceedings. The Sheriff holds that, no express right being given to the county council by the Acts in question, none can be implied. It seems to have taken 30 years to make this discovery, which means that the county councils have not been very active. Perhaps the recent reforms in the duties of the Procurators have something to do with it.

The vital statistics of Scotland for the third quarter of the year 1928 show a birth-rate of 19.1 per 1000, a marriage-rate of 7.5, and a death-rate of 11.0.

In a report to the Selkirk education authority, Dr. G. M. Elliott, the school medical officer, says that in the early part of 1928 there was a paratyphoid epidemic in Galashiels. Thirty-six children of school age were affected. All these were affected at the same time, which was easily understood as the epidemic was caused by water infection. There were no deaths among school-children from this disease.

Colonel K. H. M. Connal, chairman of the Glasgow and West of Scotland Society for the Prevention of Cruelty to Animals, has issued an appeal on behalf of Animals' Week, which is being held in the city from Nov. 18th to 24th. Among the many activities of the Society he makes special reference to work among school-children. In the Animal Defenders' Corps, instituted two years ago for children of 10 years and over, nearly 33,000 children have applied for badges of membership.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Medical Certification of Insured Persons.

A SPECIAL meeting of the Irish Medical Committee was held on Nov. 14th, under the chairmanship of Dr. Joseph Power, to consider the proposals of the National Health Insurance Commission regarding an alteration in the method of distributing the funds available for payment for certification of insured persons. As has already been stated in THE LANCET, the Commission wishes to substitute the county for the dispensary district as the area of pool which constitutes the basis of distribution. Sir Joseph Glynn, chairman, and Dr. W. J. Maguire, medical member of the National Health Insurance Commission, with some members of their staff, attended the meeting of the committee, on the suggestion of Sir Joseph Glynn, in order to explain the proposal, and to answer

any questions that might be asked. Sir Joseph, in stating his case, explained that the present method of distributing the funds by a dispensary area pool was cumbersome and difficult, and necessitated complicated calculation, so that the expense of distribution was more considerable than was justified unless there were distinct advantages in the present system which could not be retained by any other. He could find no such advantage. On the contrary, as the present method worked out, there were enormous and iniquitous differences in the payment rates for certificates issued. In the County Galway, for example, the rate for certificate varied from 1s. 5d. in one district to £1 in another. It was not uncommon in many counties to find in one district a rate for certificate six or eight times greater than in an adjoining district. This gross inequality he believed to be due to the fact that there was no accurate method of allotting insured persons to their proper dispensing districts. He had found it impossible to discover an accurate method of allotment or to establish a register of insured persons with their addresses. He understood that some medical men objected to the proposed change, but suggested a modification of his original proposal. He would be willing to take out of the county pools the towns or villages of a population of 2500 and over, and make them certification pools in the same way as urban areas of 10,000 and over are at present. In reply to Sir Joseph Glynn, it was agreed that the present method entailed more complicated book-keeping, but the committee was unable to believe that it was beyond the capacity of the staff of the Insurance Commission, with the help of the approved societies, to devise some method of establishing an accurate register of names and addresses. The objection of the committee to the proposed change was based on the grounds of efficiency. Some, at least, of the present inequality was due, not to inaccuracy in the allotment of the insured, but to laxity of certifying by certain certifiers. This laxity would be deprived of its chief check if the area of pool were increased. With a dispensary area pool, in which, as a rule, only two or three certifiers shared, each acted as a check on the others. But if the area of pool were enlarged so as to become the property of 20 or 30 certifiers, it would be impossible for any of them to exercise any check. A dishonest or careless certifier would largely increase his share at the expense of the careful certifier. Examples were given by several members present that their own receipts would fall by 50 or 75 per cent. On the withdrawal of Sir Joseph Glynn and his colleagues, a long discussion took place, and the following resolution was unanimously passed:—

"That the Irish Medical Committee decline to recommend the acceptance of the proposal of the Irish National Health Insurance Commission for revision of the scheme for distribution of remuneration for certification of insured persons, as the proposed change is likely to interfere with the efficiency of the certification system, and that the Minister for Local Government and Public Health be requested to receive a deputation from the committee to discuss the question."

Irish Medical Committee.

Some other important matters were discussed at the recent meeting of the Irish Medical Committee. The committee had under consideration a letter from the medical practitioners of the City of Cork, pointing out that the appointment of whole-time medical officers of health for the borough and county was likely to encroach on the rights of medical practitioners generally, and especially those engaged in the work of specialists, for example, in eye, ear, and throat diseases, and orthopaedics. The committee resolved:—

- (1) That the function of the health authority should be confined as much as possible to the prevention of disease.
- (2) That the work of the whole-time officer should be confined to administration and inspection, institutional or consultative.
- (3) That health visitors and nurses should be definitely responsible to a local practitioner for patients dealt with by them, including expectant mothers; and

(4) That in the case of patients other than poor persons entitled to gratuitous relief they should be always referred to their usual medical attendant to make arrangement for their medical treatment.

The committee delegated to its executive sub-committee the preparation of evidence to offer to the committee of inquiry on the working of the Local Authorities (Officers and Employés) Act, 1926.

Dublin University College Medical Society.

The opening meeting of the Medical Society of University College, Dublin, was held on Nov. 14th, in the Physics Theatre of the College. Prof. M. R. J. Hayes, President of the Society, read an address on *The Rôle of Radiology*. He gave a survey of the applications of radiology in diagnosis and treatment in all branches of medicine and surgery. A discussion followed, in which Prof. T. G. Moorhead, Senator H. L. Barniville, Prof. J. M. O'Connor, and Dr. J. B. Magennis took part.

ROYAL SOCIETY OF MEDICINE. ANNUAL DINNER.

ON Nov. 15th over 400 Fellows of the Royal Society of Medicine assembled to dine well and merrily together and, not least, to hear speeches from a statesman, a story-teller, and a man of science. Those who applied early enough to obtain tickets were fortunate indeed, for the Fellow chosen to thank these guests for coming delighted his audience, while the evening's entertainment included also a series of living pictures drawn with sure touch by their President. Lord Dawson lifted the curtain, for a moment only, on the periods when the ways of removing or alleviating pain by anæsthesia and by good nursing were revealed, gave a glimpse of the great men, past and present, commemorated during this year, noted an important recent discovery, and gave generously of the philosophy which his vast experience of medical practice has taught him.

The toast of the Society was proposed by Mr. WINSTON CHURCHILL. It was a great honour, he said, to be the fellow-guest of Mr. Rudyard Kipling. He had always been one of Mr. Kipling's greatest admirers, but the admiration had not always been reciprocal. Mr. Churchill praised the Royal Society of Medicine as one which, founded in the year of Trafalgar, had worked for the cultivation of knowledge of all parts of medicine and of the branches of science allied to it. It was just because of the unceasing expansion in the sum of human knowledge, spreading in every direction, that societies like this had now acquired a vital and essential position in the intellectual and practical life of the community. There was an increasing need of combining and focusing all the results of human study in each particular branch. The army was moving forward; we had to be sure that the furthest point reached by the most adventurous patrol at dusk was entrenched and occupied before dawn. The institution of a collective mind to cope with the knowledge which had long in its volume surpassed the capacity even of the greatest individual men was the principal reason which he would advance in proposing the toast of the Royal Society of Medicine. In its empiricism, in its continual contact with the unknown, medicine resembled in many respects the political profession. Every human being, every living body, he said, is an empire, with a population of many different races living in vast provinces under different conditions of pressure and time, subjected to accidents and misfortunes, and usually in a state of internal or external war. As long as the presiding genius, the central governing control, is seated firmly on its throne, order reigns and harmony prevails throughout the whole combination of this complex organism. But when the central power begins to weaken, or is ageing, or is opposed or undermined by

any cause, sudden or gradual, then disorder, discontent, riots, mutinies, revolts, and revolutions break out. Mr. Churchill continued: "Those in our politics see some of the diseases with which medicine grapples. Communism is a form of cancer; it is political cancer, the revolt of a single cell which subverts and throttles those immediately around it and establishes a foreign principle of life within the body politic, a principle of life governed by laws unknown to the rest of the empire, manifesting itself by most violent symptoms, and requiring remedies about which there are great differences of opinion. Some say the knife; all are agreed that the remedies should be prompt and drastic. . . . We all know the danger—I certainly do—of intervention in the affairs of a foreign country. How can anyone know all the forces that are at work, the mysterious reactions which may follow from the application of any remedy? One hopes for the best, but this intervention in the affairs of a foreign State is exactly what every doctor has to do every time he prescribes for any patient. The resources of intervention are growing, but the variety of conditions is intricate. The Royal Society of Medicine is a sort of League of Nations, applying to the disorders of the State the remedies which comprise the collective knowledge and the concerted effort of all that has been achieved by all the organisations of mankind which are directed to the purpose of human welfare."

Having spoken about the doctor's troubles in dealing with the human body and the politician's difficulties in guiding the affairs of citizens, Mr. Churchill said that they were all together that night dealing with difficulties of the government of man, and he wished to give a word of advice to their patients. He would like to say to them: "Do not be in too much of a hurry to change trusted and sober-minded advisers, or to run after the latest quack who comes up with some potent cure-all specific to wave away the ills that have racked mankind since the dawn of time. No, let us carry on this steady treatment." Here, he felt, there would be entire sympathy between the medical and political professions.

LORD DAWSON, in response, said that the Society continued to grow in wisdom, in stature, and comprehensiveness. They were proud of having been able to show the way to the world of commerce in the conception and achievement of a "merger," and without the allurements of material gain. He would not attempt to recapitulate the achievements of medicine in recent times. But he would note, as illustrations of the great part the English-speaking world had played in the development of medicine, that the arts of anæsthesia and nursing—both embodying the quality of mercy—were, both as regards their origins and highest expressions, products of the English-speaking world. Reviewing the events of the past year, Lord Dawson referred to the celebration of the tercentenary of the birth of Harvey—which brought men of learning from the world over to this country. The most notable event of the festival was the fact that, as if moved by a common sentiment, the distinguished men of all countries with one accord acclaimed Pavlov their hero. This Russian genius had in the heyday of his manhood laid the foundations of much of our knowledge of digestive processes and paved the way for the surgery of the gastro-intestinal tract. Then came the war and the revolution in his country, and he became lost from view, and at one time it was feared, from life. Yet Pavlov kept the lamp of knowledge burning and there reappeared amongst us this year this heroic figure—old now in body, ever young in spirit—who gave us some of the results of years of patient research on that new subject of conditioned reflexes which he had given to the world of thought. Lord Dawson spoke also of the growing control of tropical disease, making the Empire safe for civilisation. The Commission of Inquiry into Yellow Fever not only illustrated that theme but showed the world the spirit of medicine at its best, and the

names of Adrian Stokes, Noguchi, and William Young would always be remembered with pride. Passing from action to thought and its trend, he instanced the recent discovery that by irradiation ergosterol becomes endowed with the qualities of vitamin D. Here we had got away from the cruder conceptions of bulk and weight and were concerned with those subtler imponderable physico-chemical changes which connote the word influence. They had seen an example of irradiation to-night in the eloquence of the Chancellor, inspiring and delighting the assembly. Medicine, with the steady move of its thought towards the threshold of disease, would in the future have closer contact with man—his work and his play—and would be more concerned with his inborn qualities, physical and psychical, and his environment, and less with external attacks. They were passing, in fact, from the age of acute to subacute infections, where the host counted for more, and would think of forces rather than lesions—passing from the static to the dynamic. So it would be with the statesman; his policy would no longer be decided, still less excused, by wars and pestilence, and would have its origin in the study of the people, their qualities and needs.

Lieut.-Colonel W. P. MACARTHUR proposed the health of the guests. He spoke with eloquence of Mr. Churchill's versatility, and then of Mr. Kipling's services in the cause of Empire. Mr. Kipling's pen had raised the word "Britisher" from a contemptuous epithet to a fine title. He was accounted a poet peculiarly English, yet his love of this country was set so deep down in the soil that he was sometimes more Engländer than English, and his fairy people had their beginnings so far back in the twilight of the island that even in the title "Puck of Pook's Hill" the two essential words were pre-Saxon, relics of a language long gone by. The other guests who graced these festivities had won fame in very varied fields. Col. MacArthur concluded by admitting to a spirit of envy of all those present who could sit in the glorious assurance that they would not be called on to speak.

Mr. Rudyard Kipling's response will be found on p. 1061.

Sir ERNEST RUTHERFORD, who also replied for the guests, spoke hopefully of the future of research in medical and allied sciences. More money and more support would surely be available for this purpose, since it was becoming increasingly recognised that work on the basic sciences was necessary if any serious understanding of the functions of the human body was to be obtained. He believed that in the future every country in the civilised world would coöperate in an international attack on the diseases afflicting mankind. They would look to the British Government to join with other progressive Governments and to see that the problems were attacked in a proper and adequate way.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On Monday, Nov. 26th, at 5 P.M., at the Medical Society of London, 11, Chandos-street, Cavendish-square, W., Dr. Donald Paterson will lecture on Some Problems in Infant Feeding; on Wednesday, the 28th, at 11 A.M., at the same place, Mr. Victor Bonney will give a "gynaecological talk"; and on Thursday, the 29th, at 4 P.M., Mr. J. F. Cunningham will give a demonstration at the Central London Ophthalmic Hospital. At 2.30 P.M. on Monday, the 26th, Dr. A. J. Whiting will demonstrate at the Prince of Wales's General Hospital, Tottenham. No fee will be charged for admission to the lectures or demonstration. Special courses are now being held in urology at St. Peter's Hospital, ophthalmology at the Royal Westminster Ophthalmic Hospital, neurology at the West End Hospital for Nervous Diseases (daily at 5 P.M.), and venereal diseases at the London Lock Hospital. During December there will be two courses only—in infants' diseases at the Infants Hospital (Dec. 3rd to 15th), and in dermatology at the Blackfriars Skin Hospital. Copies of all syllabuses and information about the General Course arranged by the Fellowship may be had on application to the Secretary at 1, Wimpole-street, W. 1. The complete list of special courses for 1929 is now ready.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

The following are 1927 statistics of five administrative counties:—

Name of county and estimated (R.-G.) population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and pre-school mortality.	Diarrhea, &c., under 2 years.	Maternal mortality from childbirth.
Lancashire (1,800,300)	.. 14.6	12.7	0.78	1.34	2.7	1.9	73/37	6.6	4.9
Essex (1,024,700)	.. 16.2	10.8	0.80	1.41	2.0	1.7	51/24	4.2	3.4
Durham (996,600)	.. 20.3	12.5	1.10	0.98	2.9	1.2	96/55	7.0	5.6
Derbyshire (621,000)	.. 18.0	11.6	0.71	1.24	2.6	1.5	71/—	5.3	5.0
Hampshire (416,000)	.. 16.9	11.9	0.78	1.59	2.0	2.1	48/27	2.1	2.7

Neonatal mortality is not given in this series of reports.

Lancashire.

Dr. J. J. Butterworth expresses some dissatisfaction with the slow progress made in the pooling of isolation hospital accommodation in the administrative county, which comprises 19 municipal boroughs, 82 urban districts, and 19 rural districts—120 in all. Some of the hospitals are efficient, many are unsatisfactory, and in many the existing accommodation is not fully utilised.

For the purpose of the Milk Act the council employs 30 part-time veterinary surgeons, resident in all parts of the county, who also perform the duties under the Diseases of Animals Acts. In 12 boroughs and seven other districts the services of veterinary surgeons are available for the inspection of dairy cows, but the county council confines itself to following up tuberculous milk samples. 372 such notifications were received from local authorities, and as a result 2056 cows were examined, but the number of tuberculous animals found is not mentioned. No. 4 Clean Milk Competition was held over a period of six months, but attracted only 15 competitors. The housing conditions in 11 of the districts are described as unsatisfactory or not good; in 84 districts a shortage is reported, and in 14 there was considerable or serious overcrowding. The houses erected by local authorities numbered 4363 and other houses erected with State assistance numbered 4898. The county council has an approved scheme under the Housing (Rural Workers) Act, 1926. Up to July, 1928, 18 applications for financial assistance were received, and grants amounting to £580 were recommended in respect of five. Of the other applications 12 came to nothing and one is under consideration.

An unusual outbreak of diphtheria was reported in a Heywood family. One child at the school clinic was found to have ordinary diphtheria, and of two children at home one had both eyes affected and the other, which was the original case, a diphtheritic discharge from the ear. There were 190 notifications of small-pox and one death was registered, in the person of a tramp, who died in the union workhouse unnotified. In Dalton-in-Furness, Padiham, and Whiston, where diphtheria of a virulent type was prevalent, immunisation was found useful. The notifications of enteric fever were 123 with 26 deaths. An outbreak in an institution for boys at Widnes caused 32 cases and the only article of food on which suspicion rested was

foreign currants eaten raw. The peak year for encephalitis was 1924, when there were 299 cases and 103 deaths. During the last three years the notifications have been 178, 159, and 107, and the deaths 98, 88, and 89. The midwives sent for medical help in 37 per cent. of their cases, and the total payments to doctors amounted to £12,154, of which, according to the scale adopted, £10,370 have to be borne by the county council. No recovery is attempted when the doctor is called in on account of the babies' eyes, and £94 was paid in respect of 87 such cases. There were 208 notifications of ophthalmia neonatorum and among the survivors there was one case of total blindness and two of impaired vision.

There were two prosecutions of handywomen, but both were dismissed by the bench. In the one case the witnesses did not adhere to their proofs of evidence and in the other case the handywoman, who was engaged, was sent for at 8.30 P.M., "as labour was imminent." The doctor engaged was not sent for until after 10.15, and when he arrived everything was over. The bench considered that the defendant had acted in the best interests of her client.

Essex.

Dr. William A. Bullough expresses his satisfaction that the Ministry of Health have agreed to the long-deferred scheme of building a central institution with 150 beds for women and children suffering from tuberculosis at Black Notley, near Braintree. The Ministry of Health have now given instructions that cases of tuberculosis cannot be regarded as cured until the disease has been quiescent for two years and arrested for three years in pulmonary cases and arrested for three years in non-pulmonary cases. This, of course, upsets the comparison with past years. A determined effort is now being made in Essex to keep in touch with the contacts of open cases of tuberculosis. A pink card is issued for each of such and passed on by the infant welfare officer to the school medical officer, and ultimately sent back to the tuberculosis dispensary, with a view to re-examination from time to time. The need for X ray plant at the sanatorium in order to facilitate treatment by artificial pneumothorax has been made good. An attempt is to be made to secure a more rapid diagnosis in the case of children suspected to be suffering from pulmonary tuberculosis by their admission to the Victoria Park Hospital, for the application of all the most modern methods. It is hoped that in a few years every parish in the county will be served by a trained midwife. Though in a few districts maternity hospitals may be useful, the main effort should be, says Dr. Bullough, to ensure a safe confinement in the home. More effort is needed to secure the treatment of the defects found in school entrants during the pre-school age.

Dr. Bullough comments adversely on the scattered house-building which is going on in several of the rural districts. He is also not too favourably impressed with the L.C.C. Becontree scheme. Under this scheme since the war 17,000 houses have been built or are in course of erection in what was up to April, 1926, a parish in the rural district of Romford. The population will soon be 85,000 and ultimately 130,000, and though excellent sites were reserved for industry no industry has been begun. Dagenham is therefore a dormitory town of low rateable value for London workers. "This type of town planning," says Dr. Bullough, "has very little to commend itself." An effort is being made to get the railway companies to improve the travelling facilities between East London and Becontree. The county council have an approved scheme for the Housing (Rural Workers) Act, 1926, and of 20 applications for assistance, seven respecting 14 cottages, received total grants of £895. Two applications were not approved and 11 were under consideration at the end of the year. Complaints were received during 1927, as in many previous years, of offensive smells in the Purfleet neighbourhood, blown across the river from the sludge lagoons of the West Kent main sewage works. The dumping of London refuse on the north of the Thames at Hornchurch

has also given rise to many complaints. The refuse dumps are in the neighbourhood of the L.C.C. Becontree housing estate. The Ministry have been asked to hold an inquiry.

Durham.

Dr. Eustace Hill reports that the death-rate and infant mortality-rate were higher owing to bad climatic conditions in the first and last quarters and an unusual prevalence of influenza and respiratory diseases. The deaths ascribed to influenza numbered 496 as compared with 250 in the previous year. There were 5101 notifications of small-pox and 19 deaths were attributed to this disease, though the majority were complicated with other acute conditions. The Ministry issued regulations in January giving the county council special powers to provide hospital treatment, and these powers facilitated arrangements for pooling the available small-pox accommodation. Several patients were admitted to the Princess Mary Maternity Hospital, Newcastle, under the Puerperal Fever Regulations, but no request was received for a "second opinion," nursing assistance, or bacteriological examinations. There were 33 notifications of encephalitis and 37 deaths bearing out the truth of a previous statement by Dr. Hill that many cases of this disease are not notified.

The welfare medical officers report that the mothers do not bring the pre-school children to the centres in adequate numbers. A special dental campaign has been carried out through the centres by means of lectures, reinforced by slides, posters, and leaflets supplied by the U.K. Dental Board. The E. F. Peile Convalescent Home at Shotley Bridge has done good work for nursing mothers and their babies and pre-school children. After leaving the mothers are recommended to bring their children to the centres, but 27 per cent. failed to do so. Owing to unemployment much dried milk was supplied free at a cost of nearly £30,000. After the emergency feeding scheme ceased each applicant had to pay at least 1d. a lb. At the end of the year 5703 cases were being helped. There were 148 cases of ophthalmia neonatorum notified, and the health visitors reported 824 cases of inflammation of the eyes. The damage included one blinded baby, four with both, and one with one eye injured. There are now 74 nursing associations affiliated to the County Association. Hitherto the expensive method of sending patients to Newcastle for light treatment has been in operation, and it is now proposed to fit up the county sanatoriums with the necessary apparatus.

The housing problem remains acute; 200,000 people live in one- and two-roomed houses, the percentages of overcrowding among them being 76 and 56 respectively. Up to now the county veterinary inspector has only followed up information received as to tuberculous milks, but by this method 3286 cows were examined. The animals slaughtered for tuberculosis numbered 221, of which 69 had tubercle of the udder, 47 emaciation, and 99 other signs. The county council has now decided to appoint whole-time veterinary surgeons to carry out the various Milk Acts and Orders. The Sale of Foods and Drugs inspectors sent 40 samples of milk to be examined for tubercle, and six were found to be infected.

Derbyshire.

Dr. W. M. Ash describes the rapid progress recently made in the development of Bretby Hall Orthopaedic Hospital. It was opened in 1926 and now is fully equipped for the treatment of 55 tuberculous and eight non-tuberculous cripples. The equipment includes an operating theatre and an X ray and light department. A fully qualified teacher and an assistant teacher have been appointed and Dr. S. Hoyte, F.R.C.S., is the orthopaedic officer in residence. The building of a modern open-air block (a plan of which is given), with two 20-bed wards and one 10-bed ward, has been begun, to accommodate 50 non-tuberculous cripples, while plans for another open-air block to accommodate 32 adults suffering from non-pulmonary tuberculosis

has been approved. Chains of orthopaedic clinics for out-patient treatment are to be established throughout the county, whilst the sparsely populated portions of the county will be provided for by a motor-car service. The greatest importance is attached to the education of the children admitted as many of them have hitherto received very little education and, being cripples, they will largely have to depend for a living on their brains. Dr. Hoyte reports, for example, that the present patients include three boys aged 11, 13, and 16, who had never been to school and did not know the letters of the alphabet. Small classes and an unusually large staff of teachers will be necessary.

The midwifery service is being improved. Midwives' clubs are being formed, where the midwives can be instructed in modern methods. A successful one is already in operation at Chesterfield and five other centres have been arranged for where lectures and demonstrations can be given. A full-time woman medical officer, with extensive experience in gynaecology and obstetrics, has been appointed to conduct antenatal clinics at about 12 centres, to instruct and inspect the midwives, to investigate maternal deaths, and to supervise the council's maternity homes. Under the puerperal fever regulations nine cases were admitted to hospital, and a consultant's opinion was provided in six cases. There are five consultants in all—two in Derby, two in Sheffield, and one in Manchester. Derbyshire is well supplied with hospital accommodation, and Dr. Ash is of opinion that it is better to provide lying-in accommodation by small extensions of existing hospitals than to provide new small expensive units.

Hampshire.

Dr. R. A. Lyster reports that the county council is now the authority for the Notification of Births Act, except for the city of Winchester and the borough of Aldershot, and that notification is well carried out, the default being less than 1 per cent. The eight subsidised beds at the Winchester Maternity Society's home were used by 137 cases. The Royal Hants Hospital has an antenatal clinic twice a month, in order to sort out abnormal cases for admission to the hospital from those cases suitable for the home. All the maternity and child welfare centres are voluntary. They now number 89 and only cost the county council £600 a year. There is a growing demand for antenatal clinics and five have been established in connexion with maternity and child welfare centres. Another chief clinic, similar to that at the Hants Hospital, has been established at Basingstoke, under the charge of an obstetrician. For the purpose of the puerperal fever regulations 12 consultants have been appointed after conference with the B.M.A. division and the Panel Committee.

The working of the insurance scheme against the expense of medical help summoned by the midwives shows that under this system the doctor is much more frequently called in. Thus, during 1927 the midwives attended 5554 cases, of whom 2718 had insured and 2836 had not insured. Among the insured cases a doctor was called to 45 per cent.; among the uninsured to 25 per cent. The insured cases cost the county council £897, or 6s. 7d. each; whereas the uninsured cases cost the county £436, or 3s. 1d. each.

Most of the inspection of midwives is carried out by the superintendent of the County Nursing Association. Dr. Lyster points out that at the conferences between local authorities and the Central Midwives Board it was unanimously agreed that the post of superintendent of the County Nursing Association should be separated from that of inspector of midwives. Dr. Lyster reiterates his opinion that venereal diseases can be effectively prevented and that the facts are kept from the public by a conspiracy of silence. All but eight of the 39 districts have instructed their officers to send samples of milk to the county laboratory for tubercle examination. Positive results will be followed by veterinary examination of the herd. A table shows that 364 samples of milk were examined with five positive results. It is not mentioned whether the

examinations were microscopical or biological, and the results in the finding of tuberculous cows are not given.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED NOV. 10TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 149 (last week 122); scarlet fever, 2958; diphtheria, 1320; enteric fever, 33; pneumonia, 890; puerperal fever, 37; puerperal pyrexia, 82; cerebro-spinal fever, 8; acute poliomyelitis, 11; acute poliomyelitis, 1; encephalitis lethargica, 16; dysentery, 11; ophthalmia neonatorum, 94. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified in the following 20 counties: London, 4; Chester, 5; Derby, 21; Devon, 6 (Plymouth); Durham, 26 (of these Jarrold 16); Essex, 6 (West Ham); Huntingdon, 1; Lancaster, 7; Leicester 6 (county borough 5); Lincoln, 1; Northumberland, 1; Nottingham, 3; Stafford, 13; Warwick, 8 (Coventry); Wilts, 2; Worcester, 1; Yorks, East Riding 1, West Riding 17; Glamorgan, 13; Monmouth, 7.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Nov. 13th–14th was as follows: Small-pox, under treatment 16, under observation 2; scarlet fever, 2743; diphtheria, 1963; enteric fever, 22; measles, 71; whooping-cough, 293; puerperal fever, 14 (plus 7 babies); encephalitis lethargica, 71; poliomyelitis, 2; "other diseases," 19. At St. Margaret's Hospital there were 15 babies (plus 4 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 15 (2) from measles, 6 (2) from scarlet fever, 24 (5) from whooping-cough, 28 (9) from diphtheria, 78 (16) from diarrhoea and enteritis under two years, and 68 (18) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever outside London occurred at Bolton. Liverpool reported 3 fatal cases of measles, Walsall, Hull, and Newcastle-on-Tyne 2 each. Sunderland and South Shields each reported 2 deaths from whooping-cough. Oldham 3 from diphtheria. Deaths from diarrhoea are still high: Liverpool reports 12, Manchester 10, Stoke-on-Trent and Salford 4 each; while Glasgow, Dublin, and Belfast record 4, 4, and 6 deaths respectively for the same week. The number of stillbirths registered during the week in the great towns was 227 (corresponding to a rate of 41 per 1000 births), including 45 in London.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the committee 42 applications for grants were considered and £704 4s. was voted to 38 applicants. The following were some of the cases relieved:—

Widow, aged 62, of M.B. Since the death of her husband in 1913 the applicant has been entirely supported by her elder daughter who was doing well on the stage. This daughter died early in September, 1925, after a short illness, leaving her mother destitute and without means of support. Voted emergency grant of £10 and a yearly grant of £36 in four instalments. Other medical charities have been approached to augment the widow's income.

Widow, aged 65, of M.R.C.S. Was left penniless on the death of her husband in 1920. She has lived with her elder daughter who is a widow with one child aged 12. The daughter is earning £2 10s. a week which is the only income for these three persons. Voted £36 in four instalments.

Widow, aged 65, of L.R.C.S. For eight years after the death of her husband the applicant supported herself by letting rooms. Later she earned her living as a cook-housekeeper, but owing to her age had to give up work. She lives with her adopted daughter who receives £1 a month from her husband who is working in Canada. Voted £36 in four instalments.

Daughter, aged 52, of L.R.C.P. She is living with her brother who is only able to earn £71 10s. and lives rent free in three rooms. On many occasions it has been found that the applicant was practically starving. Voted £26 in four instalments and clothes to be supplied by the Guild. The local Council of Social Welfare is interested in this case.

Subscribers and donors are asked to forward their subscriptions for the current year before Dec. 31st, 1928. Not only the scope of the Fund's work, but also the amount of assistance given depends upon the subscriptions received, and in view of the many cases in which help is greatly needed, especially during the winter months, an urgent appeal is made for contributions. Cheques should be sent to the hon. treasurer, 11, Chandos-street, Cavendish-square, London, W. 1.

Correspondence.

"Audi alteram partem."

THE DERATING OF HOSPITALS.

To the Editor of THE LANCET.

SIR,—I would suggest that the governing bodies of hospitals should consider seriously the expediency of appealing for hospitals to be brought within the derating provisions of the new Local Government Bill. Their need is great, the justice of such a course is evident, and I do not propose to take up your space by adducing arguments. It is essential to act without delay.

I am, Sir, yours faithfully,
Buxton, Nov. 17th, 1928. CHARLES W. BUCKLEY.

THE HÆMOGRAM.

To the Editor of THE LANCET.

SIR,—The papers on the blood and Arneth counts you have been recently publishing and an excellent paper in the *Journal* of the Royal Naval Medical Service for October, by Surgeon-Commander W. I. Gerrard, who (quoting Piney) refers to Schilling, encourage me to say a word on Schilling's hæmogram. Both this and his work on the blood picture are too little, I venture to think, known in England. An assistant in Berlin University, he contributed the section on Blood Examination to the great Tropical Diseases Handbook, has written a book on "The Blood Picture" (now in its sixth edition) and two students' guides, one on general blood study, the other on the deep drop (each in its third edition)—evidence that his work is appreciated in Germany.

Schilling takes the view that the normal blood picture is a cell complex of highly differentiated cells, ripened though not of equal age, in very constant proportion, altered at one end by degeneration or loss (i.e., hæmorrhage), at the other by regeneration, the work of the blood-forming organs, bone-marrow (red cells and granulocytes), lymphoid tissue (lymphocytes), and the reticulo-endothelial tissue especially of the spleen and liver (monocytes). Disease alters these organs and the variation in their output shows in the blood. There is normally a definite point in development at which these cells are drafted into the circulation. When irritation occurs, replacement is needed, and as this need increases, the barriers to the circulation are lowered further and further and cells are sent out less and less mature. This immaturity is shown by the Arneth count, but red cells, eosinophiles, &c., must also be considered, and to make this easy, to ensure that none is overlooked, is the purpose of the hæmogram.¹ This, when completed, shows red and white count, hæmoglobin, deep drop, parasites, and so on; the white cells are charted in great detail, basophiles, eosinophiles, neutrophiles, four groups—(a) myelocytes; (b) metamyelocytes with round nuclei ("immature"); (c) metamyelocytes with notched nuclei ("band-form"; I submit "ribbon-like" is more what is meant, like a capital U, the nucleus the same thickness all along; (d) multilobed polymorphs. The names "immature," "band," and "multilobed" are from Admiral Stitt's book in which they first, so far as I know, got English names. Ordinarily there are 4 of (c) to 63 of (d). As the need for replacement increases and the reserves are hurried up, more and more (c) appear; perhaps (b), even (a). This is "the shift to the left," measured by the fraction $\frac{a+b+c}{d}$; in a blackwater case it may be $\frac{21+21+16}{28}$

or 2. Other showings must be taken into account. Of three cases of acute pyrexia with leftward shift and leucopenia one might be a malarial relapse, shown by polychromasia of the red cells, one sand-fly fever, with a very characteristic leftward shift;

dengue shows less leucopenia, less leftward shift, no polychromasia. The hæmogram also gives warning of such complications as sepsis, hæmorrhage; the blood reacts more quickly than the temperature. Like the findings of auscultation, those of the hæmogram are not always easily interpreted, but experience will help. As Schilling says, it is not the blood which deceives. He wishes the clinician to tell the pathologist his (clinical) diagnosis of the case, when the clinician will be informed whether that seems probable, possible, or unlikely to the pathologist, for thus it is easy to have an objective check on diagnosis. Unexpected conditions may come to notice, of which he gives examples.

I regret I can myself say no more, as Schilling's book came my way only after I had ceased to work in laboratories. But I submit his method is very valuable.

I am, Sir, yours faithfully,
Kew, Nov. 18th, 1928. W. E. HOME.

SALVARSAN TREATMENT OF ANTHRAX.

To the Editor of THE LANCET.

SIR,—In discussing the chemical treatment of anthrax in your Modern Technique series Dr. Adrianus Pijper, after pointing out the importance of neosalvarsan in anthrax, writes: "The salvarsan treatment of anthrax has never failed us yet, although its theoretical foundation may be lacking." In my opinion the explanation is this. Neosalvarsan is a chemotherapeutic substance. According to Ehrlich these substances possess haptophoric and toxophoric groups. After absorption by the blood cells haptophoric groups of neosalvarsan combine with the chemo-receptor groups of the micro-organisms, while the toxophoric groups exercise baneful influence over the bacteria. The factor of stimulation may come in, as well as that of immunity. Arsenic compounds, like those of antimony, belong to a group which wields wide influence on various infections of different ætiology, while the amount of active immunity is, as we know, more marked during the beginning of infection. I think the action is bacteriotoxic rather than bactericidal.—I am, Sir, yours faithfully,

P. V. KARANCHANDANI, M.B., I.M.S.,
In charge, Indian Military Hospital, Pishin
(Baluchistan), India.
Oct. 23rd, 1928.

"FEE-SPLITTING."

To the Editor of THE LANCET.

SIR,—According to the legal reports in the *Times* of Oct. 25th a lady who is principal of the Radiant Health Institute said in evidence that she was sent cases by many leading specialists, and that these gentlemen shared her fees. This statement might very well be ignored but for the unfortunate fact that three of the foremost and most respected names of the profession appear in the report in very close juxtaposition to this allegation. Probably these gentlemen felt the matter to be beneath their notice, but would it not be very desirable that they should publish a short disclaimer or require the lady in the case to make it quite clear that she was not referring to them?

I am, Sir, yours faithfully,
DONALD M. O'CONNOR.
Malmesbury, Wilts, Nov. 7th, 1928.

* * * There are charges too wild to need refutation. Dr. O'Connor has perhaps taken the case of McCalman v. Walton (*Times*, Oct. 25th) too seriously. Plaintiff complained that defendant's "Radiant Health Institute" had failed to give her a continuous course of "curative rhythm" because defendant was preoccupied with a project for rejuvenating elderly ladies at £500 apiece. Defendant admitted she had had this golden vision; a medical practitioner was to help her and three distinguished specialists (whom she named) would send patients and share fees; but she added regretfully that the project never got beyond the visionary stage.—ED. L.

SHAKESPEARE'S DOCTORS.

To the Editor of THE LANCET.

SIR.—It would be interesting to know upon what grounds Sir StClair Thomson (as reported in your issue of Nov. 10th, p. 977) thinks that Shakespeare had "rather made fun of doctors up to King Lear." As a matter of fact, Shakespeare shows far more consideration for the medical profession than does any of his contemporary dramatists. Possibly Sir StClair Thomson had in memory the Pinch of the "Comedy of Errors" and Dr. Caius of the "Merry Wives," but when it is borne in mind that in both these plays Shakespeare was merely working upon older material (as is so ably shown by the Rt. Hon. J. M. Robertson in his "Canon of Shakespeare," Part II., and his "Problem of the Merry Wives of Windsor") in which he probably had no alternative but to retain certain comic parts dear to the groundlings, he can hardly be made responsible for the anachronism Pinch or the caricatured Frenchman, Shakespeare's own doctors are Dr. Butts (introduced for a brief moment into the last act of "Henry VIII." in a strictly non-professional character), who does not count, since he is probably introduced by Fletcher, Dr. Cornelius of "Cymbeline," and the deceased Gerard de Narbon in "All's Well," all worthy men and not "made fun of." Further, there are the unnamed doctors in "Macbeth" and "Lear," also worthy and serious delineations. As to references to the profession, it is true that in "Much Ado" (v., scene i.) there occurs: "Then is an ape a doctor to such," but here, as in many other passages (the word "doctor" occurs 64 times in Shakespeare, but in the medical sense in 46 only), it means a "learned man." Nor in the 29 passages containing the word "physician" can I find one in which the title or the calling is ridiculed.

It is very different when one comes to consider the other Tudor dramatists. I have a list of 29 named and unnamed doctors culled from the works of Ford, Jonson, Webster, Tourneur, Massinger, Greene, Fletcher, Beaumont, Marlowe, Middleton, Dekker, and Chapman, excluding surgeons. Of these, some are good fellows and good doctors; others, like Eudemus, in "Sejanus," and Lecure, in "Thierry and Theodoret," are scoundrels, panders, and poisoners; Alibius, in "The Changeling," keeps a very doubtful private asylum, and the unnamed physician in "The Fair Quarrel" is one of the lowest blackguards to be found in any play. In no work of Shakespeare can be found such a passage as the remark of the "Spanish Curate":

"The doctors are our friends; let's please them well;
For, though they kill but slow, they are certain."

or that in "The Lover's Melancholy":

"Thou art in thy religion an atheist, in thy condition a cur, in thy diet an epicure, in thy lust a goat, in thy sleep a hog; thou takest upon thee the habit of a grave physician, but thou art indeed an impostorous empiric. Physicians are the cobblers, rather the botchers, of men's bodies; as the one patches our tattered clothes, so the other solders our diseased flesh."

A knowledge of the works of his contemporaries adds greatly to one's appreciation of Shakespeare. There is no physician among their characters that can compete in delineation with, say, the unnamed man who ministers to Lear, or the wise Cornelius who circumvents Cymbeline's vile queen, or the Scottish doctor who has to face Macbeth. They are as different as is Shakespeare's soaring, Pegasus-like verse from the pedestrian lines of his brother playwrights, even from "Marlowe's mighty line." To paraphrase a modern poet: "What do ye know of Shakespeare Who only Shakespeare know?"

I am, Sir, yours faithfully,

Wimpole-street, W., Nov. 10th. MACLEOD YEARSLEY.

ST. MARY'S HOSPITAL, PLAISTOW.—The Lord Mayor of London has opened the first section of the new out-patients' department which has cost £10,000. The section includes an accident receiving room, casualty, general and ophthalmic operating theatres and the necessary concomitants, and accommodation for five extra accident cases.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

LOCAL GOVERNMENT (SCOTLAND) BILL.

THE Local Government (Scotland) Bill, which has been introduced in the House of Commons by Sir JOHN GILMOUR (Secretary of State for Scotland), is divided into four parts. Under Part 1 the county councils (as reconstituted) and the town councils of burghs having a population of more than 20,000 will become the authorities for poor-law, lunacy, and mental deficiency, major health services, classified roads, and certain other services. Among the bodies that will disappear after the passing of the Bill are parish councils (the existing poor-law authorities) and district boards of control (who are at present charged with the administration of the Lunacy and Mental Deficiency Acts). Where a district board have provided a district asylum the county councils and the town councils of the large burghs within the district are treated as having combined for carrying on the asylum. With certain unimportant exceptions the expenses relating to the transferred functions will be charged over the whole area of the county or large burgh, and not on the basis of the parish or district as hitherto. Among the principal matters with which the enactments set out in Part 1 of the First Schedule deal are: Infectious diseases (including tuberculosis and venereal disease), maternity service and child welfare, milk and dairies, adulteration of food and drugs and unsound food, and town-planning. The first four categories may be described as the major health services. Clause 11 contains further provisions with regard to combinations of local authorities. Such combinations may be voluntary, but where combination would be of public or local advantage it may also take place as a result of an Order by a Central Department, such as the Secretary of State, the Scottish Board of Health, and the General Board of Control for Scotland. Compulsory combination of authorities can take place only on the application of one of the authorities. In counties there must be a committee for poor relief, and a provision is inserted permitting any council to include in any committee or subcommittee persons who are not members of the council so long as at least one-half of the members are members of the council. No council is allowed to delegate to a committee any function relating to raising money by rate or loan or incurring capital expenditure. Clause 13 permits a county council to delegate certain functions to the town council of a small burgh on terms to be agreed upon. Under Clause 18 the limit of 1s. per £, which still applies in counties to the public health general assessment, is repealed. Clause 19 makes it compulsory on every rating authority instead of levying separate rates for poor relief, public health, and so forth over the whole area of the authority to levy a consolidated rate. Clause 24 empowers a county council to give financial assistance to any special district (e.g., for water or drainage) where the district in their opinion is unable to bear the whole expense unaided. Clause 25 provides that if the town council of a small burgh fail to discharge their duties with regard to water-supply, drainage, or housing (which duties are not being transferred by the Bill to county councils), or any other public health duties, the Scottish Board of Health may empower the county council to discharge the duty at the expense of the burgh for such period as may be specified. Clause 26 provides that when a vacancy occurs in the post of medical officer of health or sanitary inspector of a small burgh the county medical officer of health or sanitary inspector shall be appointed to the appropriate vacancy unless the Scottish Board of Health otherwise agree.

NEW BILLS.

In the House of Lords on Wednesday, Nov. 14th, Lord DARLING presented a Bill for the preservation of infant life. In the House of Commons on the same day Sir R. GOWER presented a Bill to prohibit the vivisection of dogs. Both measures were read a first time.

EXPIRING LAWS CONTINUANCE BILL: THE TWO-SHIFT SYSTEM AND WORKERS' HEALTH.

On Friday, Nov. 16th, the House of Commons went into Committee on the Expiring Laws Continuance Bill, Mr. HOPE (Chairman of Committees) in the Chair.

Mr. RHYES DAVIES moved an amendment to omit the continuation of Section 2 of the Employment of Women, Young Persons and Children Act, 1920. About 800 orders, he said, had been issued under this clause, and they would soon reach the stage when all the workpeople in the country would be employed under the two-shift system, which would be a terrible state of things indeed. The proof that the system was never intended to continue beyond the war period was to be found in the section itself which provided

that it should be abolished on Jan. 1st, 1928. The continuance of this section was, in fact, torpedoing the Factory Act of 1901 by destroying one of its main provisions.

Miss BONDFIELD said that she had received some very pathetic letters addressed to her, not as a Member of Parliament, but as the chief woman officer of her own trade-union. She had a number of letters from mothers in which they made reference to the injury done to the health of their daughters. It seemed to her that it was the policy of the Home Office deliberately to encourage the establishment of the two-shift system. She supported wholeheartedly the demand for the withdrawal of the section.

After further debate,

Sir W. JOYNSON-HICKS (Home Secretary) said that the clause did not involve women and young persons working more than eight hours a day. It meant running a factory for 16 hours in two shifts of eight hours each, and there was a large amount of evidence in the possession of the Home Office that at periods of pressure it was better for the health of the workers to work under those conditions than to work overtime. An order was granted only after a very full and special inquiry had been made by the factory inspector as to whether the workers desired it, and consideration of whatever recommendations the inspector made in his report to the Home Office. Speaking generally, the standard of welfare in factories where the two-shift system was in operation was distinctly above the average of factories generally. After the Order was made the factory had to be visited at least once every quarter by the factory inspector. The number of Orders granted was 786 in respect of 681 works, but, so far as he could gather, not more than one-third of the total were at work at any one time. No hon. Member had put before him any evidence that the health of the workers suffered by reason of the two-shift system. He found that workers often applied to be put on the system, and that except in certain specified cases the women had not complained of the work, and were more than satisfied to go on with the system. The Medical Research Council and the Industrial Fatigue Board had made a very careful investigation into the consequences and effect of the two-shift system. They stated in their report that no conclusive evidence had been found of a greater amount of sickness on one side or the other. In three out of four typical factories investigated the Board reported that the workers preferred the shift work to the day work. He thought that it was an experiment well worth proceeding with.

The amendment was negatived by 122 votes to 106—Government majority 16.

CLOSING OF HAIRDRESSERS' SHOPS ON SUNDAYS.

On Tuesday, Nov. 20th, Mr. JAMES STEWART asked leave to introduce a Bill to provide for the compulsory closing of hairdressers' and barbers' shops on Sundays. He explained that the Bill, which he has introduced on several previous occasions, dealt with what was a dangerous trade. The conditions under which the people in the barbers' shop worked were injurious to their health. In a great many instances, the shops were unhealthy places, and if there was a proper standard of inspection many of them would not be allowed to carry on. The workers in this trade worked longer hours than did the average shopkeeper, the average being from 60 to 70 per week. In 1914, one out of every five of the persons engaged in the trade died of consumption, and to-day, if Members went to a barber's shop, they must remember that one out of five of the men who looked after them were sources of infection.

Leave was granted to bring in the Bill, which was read a first time.

HOUSE OF COMMONS.

WEDNESDAY, NOV. 14TH.

Scottish Local Authorities and Rating Reform.

Mr. SHINWELL asked the Secretary of State for Scotland how many local authorities had made representations to him expressing opposition to the proposed changes in local government in Scotland, and how many had stated their views in support.—Sir J. GILMOUR replied: I have received representations from 44 local authorities against, and from 20 local authorities in favour of, the Government scheme as a whole. In some cases representations in favour are conditional on amendments, more or less extensive, being made in the scheme, or on the new grants being adequate. I have also received a number of representations from local authorities as to details of the scheme.

Direct Sunlight in School Buildings.

Sir CHARLES TREVELYAN asked the President of the Board of Education why the Board had recently insisted on certain local education authorities, against their wishes, putting windows into their schools admitting direct sunlight;

and whether, in view of the difference of expert opinion in the matter, he would allow local authorities discretion to experiment in this relatively small problem of school planning.—Lord E. PERCY replied: The authorities in question proposed to erect premises into which direct sunlight could never penetrate. Since, by the use of a blind, it will still be possible to exclude direct sunlight when desired, I do not think that there has been any unreasonable interference with the authorities' discretion. Experiment is good, and, as the right hon. Member must be aware, the rigidity of the Boards' building regulations has been very greatly relaxed during the last three years; but the essence of an experiment is that it may fail, and the experimenter should be careful to leave a way open for retracing his steps.

Salaries of Post Office Medical Officers.

Dr. LITTLE asked the Postmaster-General if he was aware that salaries paid to officers in the post-office medical service were lower than in any other Government department, and that it was the only department in which unequal rates of payment as between men and women obtain, and if he proposed to take suitable action in the matter.—Viscount WOLMER (Assistant Postmaster-General) replied: The salaries of the officers in question were recently the subject of a claim before the Industrial Court, who have referred the matter back to the parties for reconsideration. Pending further developments, I cannot make any statement on the matter.

THURSDAY, NOV. 15TH.

Assessment of War Pensions for Deafness.

Mr. R. MORRISON asked the Minister of Pensions whether there was any fixed rate of disability for an officer or man who was rendered stone deaf by head wounds; and whether, in fixing his rate of disability, any consideration was given to his pre-war occupation.—Major TRYON replied: The rate for total deafness caused by war service is fixed at 70 per cent. by the Royal Warrant. In the case of deafness, as of other disabilities, assessment is, in the interests of pensioners, uniformly in accordance with the degree of physical disablement, without regard to the fitness or unfitness of the pensioner for any particular occupation.

Milk Adulteration in Brecon.

Dr. VERNON DAVIES asked the Minister of Health if he was aware that in 1924 the county of Brecon, under the Sale of Food and Drugs Acts, examined only four samples of milk, of which three were found to be adulterated, and in 1925 they examined eight samples, all of which were found to be adulterated, and that in the years 1926 and 1927 no samples of milk were examined, in spite of the evidence of the unsatisfactory results of the previous two years; and what steps had been taken to draw the attention of the county authorities to these facts, and what reply, if any, had been made to such representation.—Mr. CHAMBERLAIN replied: So far as regards samples submitted to the public analyst the facts are as stated in the question. It is the practice in this county to have most of the milk samples tested informally by the inspectors, and only to send samples to the public analyst where the results of the informal tests show reason to suspect adulteration. During the four years in question over 1100 samples were tested by the inspectors in the county of Brecon. I have impressed on the county council the importance of submitting an adequate number of unsuspected samples to the public analyst, and they have promised that in future a certain number of samples will be regularly submitted to him.

Block Grants for Maternity and Child Welfare.

Mr. W. THORNE asked the Minister of Health if he was aware that the Association of Infant Welfare and Maternity Centres, representing 1200 local centres, had passed a resolution protesting against the proposals for reform in local government with respect to the substitution of block grants in support of maternity and child welfare service; and whether the views of this Association would be taken into consideration before the matter was brought before the House.—Mr. CHAMBERLAIN replied: The answer to the first part of the question is in the affirmative. The proposals of the Government in this matter are already before the House, and should, I think, completely dispel any fears lest the maternity and child welfare service should suffer by the changes foreshadowed.

Reconstituted Cream Bill.

Mr. EVERARD asked the Minister of Health whether he proposed to introduce the Reconstituted Cream Bill during the present session.—Mr. CHAMBERLAIN replied: I regret that it will be impossible to find time for such a Bill this session.

Maternity and Child Welfare.

Mr. WEBB asked the Minister of Health the total number of local health authorities which might take action under

the Maternity and Child Welfare Act, 1918, and also the approximate number of such authorities, distinguishing between county boroughs, county councils, urban districts, and rural districts, that had submitted for his sanction under that Act arrangements for provision for expectant and nursing mothers and children under 5 years not in attendance at school.—Mr. CHAMBERLAIN replied: The following is the information asked for: There are 1856 local health authorities (including county councils) in England and Wales which are empowered to take action, with the sanction of my department, under the Maternity and Child Welfare Act, 1918. Provision has been made for maternity and child welfare in every sanitary district in the country, either by the county council or the local sanitary authority. The authorities at present making provision are 60 county councils, 83 county borough councils, 150 borough councils, 135 urban district councils, and 18 rural district councils.

Mr. MONTAGUE asked the Minister of Health the terms of the recent circular to local authorities intimating a maximum expenditure which would be recognised for grant-in-aid of the supply of milk for expectant and nursing mothers and children; to which authorities the circular was sent; and the estimated saving to the Treasury.—Mr. CHAMBERLAIN replied: No such circular has been issued, but in the letters which were sent to some local authorities last March, informing them of the maximum expenditure for maternity and child welfare work during the current financial year which could be recognised for grant, certain suggestions as to procedure were made, with a view to enabling the authorities to keep their expenditure on milk within the amounts approved for grant. This letter was sent only to the authorities whose estimated expenditure on milk exceeded £100, and, moreover, was not addressed to those whose districts are situated in distressed mining areas in Durham, Lancashire, Northumberland, and South Wales. The total estimated saving in grant is about £12,000.

Prescription of Liver Extract to Insurance Patients.

Mr. AMMON asked the Minister of Health whether panel doctors might prescribe liver extract in cases of pernicious anæmia; and would such be accepted as a legitimate charge on the National Health Insurance Fund.—Mr. CHAMBERLAIN replied: The decision of the question whether this or other preparations can be regarded as drugs or medicines within the meaning of the National Health Insurance Acts rests primarily with insurance committees. But, in response to inquiries made on behalf of committees, I have indicated that there is nothing before me to suggest that this preparation could properly be regarded as being excluded from the scope of medical benefit in any cases in which it is requisite for the patient's treatment.

Claims for Sickness, Disability, and Maternity Benefits.

Mr. RHYS DAVIES asked the Minister of Health whether the claims for sickness, disability, and maternity benefits from approved societies were now decreasing or otherwise; and if he would show the amounts on the basis of comparisons for previous periods.—Mr. CHAMBERLAIN replied: The following statement gives an approximate comparison of the benefit expenditure of approved societies in England and Wales in 1926 and 1927, with the expenditure in 1925. Allowance has been made for variations in additional benefits, &c., in order to make the figures for the various years as far as possible comparable.

		Percentage ratio of expenditure in undermentioned years to expenditure in 1925.	
		1926.	1927.
		Per cent.	Per cent.
Sickness	{ Men ..	116	113
	{ Women ..	108	112
Disability	{ Men ..	113	121
	{ Women ..	114	126
Maternity	{ Men ..	95	90
	{ Women ..	105	103

Complete information relating to 1926 to date is not available, and direct comparison with previous years is impracticable owing to the cessation, since January last, of the right to sickness and disablement benefit in the case of persons over age 65. An examination of the expenditure of certain large societies in the first half of 1928 indicates broadly, after allowing approximately for the above-mentioned cessation, that the expenditure on sickness benefit in this period was rather less than in the corresponding period of the preceding year in the case of both men and women. In this connexion it will be appreciated that a severe influenza epidemic materially affected the claims in the early months of 1927. The cost of disablement

benefit was, however, somewhat heavier in 1928 in respect of each sex.

Poor-law Statistics.

Sir WALTER DE FRECE asked the Minister of Health the proportion of the estimated population in receipt of poor-law relief on Jan. 1st, 1914, and in each of the last 10 years.—Mr. CHAMBERLAIN replied: The proportion per 10,000 of the estimated population of all persons in receipt of poor-law relief on or about Jan. 1st in the years 1914, and 1918 to 1928 was as follows:—

Year.	Rate per 10,000*	Year.	Rate per 10,000*	Year.	Rate per 10,000*	Year.	Rate per 10,000*
1914	208	1920	154	1923	403	1926	370
1918	156	1921	177	1924	357	1927	396
1919	148	1922	394	1925	311	1928	347

* Rate per 10,000 of estimated population, of persons in receipt of poor-law relief.

Sir WALTER DE FRECE asked the Minister of Health the total number of casuals relieved in England and Wales in 1914, and in each of the last ten years.—Mr. CHAMBERLAIN replied: The following statement shows the number of casuals in receipt of poor-law relief in England and Wales on or about Jan. 1st in the years 1914, and 1919 to 1928:—

Year.	Casuals.*	Year.	Casuals.*	Year.	Casuals.*
1914	7,568	1922	6,572	1926	8,294
1919	1,091	1923	7,628	1927	10,737
1920	2,035	1924	7,794	1928	10,497
1921	4,084	1925	7,664		

* Number of casuals in receipt of poor-law relief.

Mr. DUCKWORTH asked the Minister of Health what proportion of the rates per head paid in the years ending March 31st, 1914, 1924, 1925, 1926, and 1927 were for the relief of the poor, and purposes connected therewith; and how much for other purposes.—Mr. CHAMBERLAIN replied: The following statement gives the desired information:—

Year ended March 31st.	Average amount of rates collected per head of estimated population.		
	For relief of the poor and purposes connected therewith.*	For all other purposes.*	Total.
1914 ..	s. d. 6 5	£ s. d. 1 12 6	£ s. d. 1 18 11
1924 ..	16 11	2 17 8	3 14 7
1925 ..	16 1	2 17 2	3 13 3
1926 ..	16 2	3 0 3	3 16 5
1927 ..	19 2	3 2 6	4 1 8

* Approximate.

Overcrowding at the Newington Institution.

Mr. DAY asked the Minister of Health whether his attention had been drawn to the inadequate accommodation and overcrowding at the Newington Institution, particularly with reference to the shortage of hospital beds where serious overcrowding had taken place each winter for several years past; and in view of the fact that certain essential improvements in the receiving wards, nursery, and other receiving departments of the Newington Institution had been repeatedly urged by the inspector of the Ministry of Health, what steps his department were taking in the matter.—Mr. CHAMBERLAIN replied: I am aware that some additional accommodation is required at this institution, but I am unable at the present time to contemplate the approval of the scheme that has been submitted by the Southwark Board of Guardians, which involves an expenditure of at least £100,000. My officers have already made suggestions designed to meet the immediate needs of the institution.

Artificial Light Treatment for School-children.

Dr. VERNON DAVIES asked the President of the Board of Education what steps he took to provide that artificial light treatment for the school child was only given by properly qualified persons.—Lord E. PERCY replied: In many cases artificial light treatment for children attending public elementary schools is provided at the light department

of a general hospital under an arrangement between the local education authority and the hospital authorities. Treatment at a school clinic is allowed only on condition that a medical officer with special experience of artificial light therapy will be in charge, and that he will be assisted by a nurse who has also had special experience of this work.

Tuberculosis in the Navy.

Sir A. SHIRLEY BENN asked the First Lord of the Admiralty whether the rules and principles governing the assessment of attributability in tuberculosis cases in the Royal Navy had been investigated; and, if so, what decision had been reached by the Board of Admiralty.—Lieut.-Colonel HEADLAM (Parliamentary Secretary to the Admiralty) replied: The Board of Admiralty have made the most careful and exhaustive inquiry into the incidence of tuberculosis in the Navy with particular reference to the question whether, in the matter of pension awards following invaliding for this disease, there is adequate recognition of causes peculiar to the conditions of naval service afloat to which tuberculosis might be regarded as attributable. As a result of this investigation they have come to the conclusion that although the rules and principles governing the assessment of attributability in tuberculosis cases have in the past been correctly formulated there are grounds justifying more generous treatment in many of these very distressing cases, and they have decided that in respect of invalidings as from Oct. 1st last there should be such a modification of these rules and principles as will very considerably reduce the percentage of cases in which "non-attributable" awards only can be regarded as appropriate. These arrangements are, of course, without prejudice to the consideration of any recommendations which may be embodied in the report on this question which is expected shortly from the Joint Medical Services Committee.

Small-pox in the Army.

Mr. KELLY asked the Secretary for War whether he was now in a position to publish the statistics of the small-pox cases and deaths recorded in the British Army in every part of the world during the years of the war.—Sir L. WORTHINGTON-EVANS replied: The official History of the War (Medical Services, Hygiene of the War, Vol. II.) gives a good deal of general information as to small-pox. A statistical volume of the medical history of the war is in course of preparation, but I am unable to say to what extent it will be possible to deal with the statistics of any particular disease.

MONDAY, NOV. 19TH.

Government and Radium Supplies.

Sir H. BRITAIN asked the Prime Minister whether, in view of the increased demand for radium for curative purposes and of the uneconomical character of purchases of small quantities by institutions, he would consider rendering Government assistance in obtaining supplies.—Sir K. WOOD (Parliamentary Secretary to the Ministry of Health) replied: The whole question of the radium requirements of this country in relation to present sources of supply is at present under consideration by a subcommittee of the Committee of Civil Research.

Use of Electrotherapy.

Dr. VERNON DAVIES asked the Minister of Health if his department was in any way responsible, by means of grants or otherwise, for the use of electrotherapy in the treatment of disease; and, if so, what steps were taken to insure that the treatment was only given by properly qualified persons.—Sir K. WOOD replied: Yes, Sir. Electrotherapy is practised in public institutions dealing with tuberculosis, with maternity and child welfare, and with the care of the pauper sick. It is a condition of any grant that the medical officer using such means of treatment should be specially qualified or experienced, and the treatment provided in a poor-law institution is always under the direction of a qualified medical practitioner.

TUESDAY, NOV. 20TH.

Smoke Abatement.

Commander BELLAIRS asked the Minister of Health whether he could make a statement as to any progress achieved as the result of the Public Health (Smoke Abatement) Act, 1926.—Mr. CHAMBERLAIN replied: There are now five Regional Advisory Committees, including one for Greater London, and one Executive Committee with administrative powers. An Order has been made bringing new processes under the operation of the Alkali Act. By-laws as to the emission of black smoke have been approved for a number of local authorities, and generally there is a marked

quickenings of interest and activity in the work of smoke abatement.

National Health Insurance Contributions.

Mr. RILEY asked the Minister of Health the respective contributions of the State, the employers, and the insured persons to the National Health Insurance Fund for the year 1927-28.—Sir K. WOOD replied: As the National Health Insurance Fund accounts are made up for calendar years, figures for the financial year are not readily available. For the year 1927 the approximate contributions of employers and insured persons in England and Wales were: Employers, £11,866,000; insured persons, £11,748,000. The State contribution, which represents the statutory proportion of the cost of benefits and administration, together with the cost of central administration, was, in 1927, £6,842,000.

The Price of Milk.

Mr. R. MORRISON asked the Minister of Agriculture the total annual additional sum which would be charged to the milk consumers of the metropolitan area under the recently arranged agreement between the milk distributors and the National Farmers' Union.—Mr. GUINNESS replied: It has been stated that the retail price charged by distributors will be increased by 1d. per quart in the months of April and September, 1929. The consumption of milk per head per day in this country has been estimated at approximately one-third of a pint, and on this basis the additional average cost would be 10d. per head for the two months. Taking the population of Greater London at 7,810,000, this is equivalent to £325,400.

Obituary.

EDWARD KNIGHT, M.R.C.S., L.S.A.

ON Oct. 26th died Edward Knight, who was for long a senior demonstrator, chief assistant, and subsequently sole director of Cooke's School of Anatomy in Handel-street, London. It will be remembered that at the end of last century this establishment was the only private medical school in the United Kingdom which was licensed to keep a dissecting room and recognised to take students during the curriculum. Edward Knight was born in 1859, pursued his medical studies at University College and Middlesex Hospitals, and qualified L.S.A. and M.R.C.S. in 1889. He specialised early in anatomy, for his book, "A Plea for Practical Anatomy," was published not many years after he became qualified, and most of his life was spent in the dissecting room and lecture theatre. Many who were not necessarily idlers are still grateful for the help in their anatomy afforded them at "Cooke's School." The extraordinarily systematised and intensive courses allowed of a rapid survey of the naked-eye anatomy in the shortest possible space of time. Edward Knight was exceptionally gifted in carrying on instruction by means of quick question and answer on the dissected part. He was of a cheerful, even jocular, disposition, and had a handsome and somewhat commanding person. He was, therefore, well adapted to hold the attention of those who had least "learnt to learn," while many candidates for the Primary Fellowship found it helpful to be put rapidly through their paces by this energetic and sprightly coach.

Sir James Dundas-Grant writes: "Knight had naked-eye anatomy at his fingers' ends and knew Cooke's wonderful tablets through and through. These 'tablets' presented pretty solid doses of anatomy in a most condensed form, in which the regional and systematic methods were cleverly blended. The work for the teacher was extremely hard, and there is every probability that the strain, even on this vigorous man, led to the progressive muscular atrophy which after a considerable number of years of poor health led to his death."

Many of his pupils have no doubt predeceased him, but there must be still a number remaining who will remember him with gratitude.

Medical News.

UNIVERSITY OF OXFORD.—An examination for a Radcliffe Travelling Fellowship, of the annual value of £300 and tenable for two years, will be held during Hilary Term, 1929, at the University Museum, commencing on Feb. 12th at 10 A.M. Candidates must have passed all the examinations required by the University for the degree of Bachelor of Arts and for the degree of Bachelor of Medicine, the latter within the last four years. The successful candidate must devote himself during the period of his tenure of the Fellowship to the study of medical science and to travel abroad with a view to that study. At the examination papers will be set in physiology, pathology, and preventive medicine, and a subject will be proposed for an essay. There will also be a practical examination in pathology. Intending candidates should send their names, addresses, and qualifications to the Regius Professor of Medicine, University Museum, on or before Jan. 30th.

UNIVERSITY OF LONDON.—Prof. G. E. Gask has been elected Dean of the Faculty of Medicine for the period 1928-30, and Prof. L. N. G. Filon Dean of the Faculty of Science.

OLD EPSOMIAN CLUB.—The annual dinner of this club will be held at the Trocadero Restaurant, Piccadilly-circus, at 7.30 P.M., on Thursday, Dec. 13th.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.—The next quarterly meeting of this Association will be held to-day (Friday), Nov. 23rd, at the British Medical Association House, Tavistock-square, London, W.C., under the presidency of Prof. J. Shaw Bolton, when a discussion will be held on certain points raised in papers on general paralysis read by Dr. J. Brander and Dr. J. F. Smyth at the annual meeting.

ANTENATAL METHODS WITH SPECIAL REGARD TO DISPROPORTION.—A discussion on this subject will be held at a meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health at the Royal Free Hospital, Gray's Inn-road, London, W.C., to-day, Friday, at 8 P.M. Prof. L. McIlroy, Mr. Eardley Holland, Prof. F. J. Browne, Dr. Annie McCall, Mr. Aleck Bourne, and Mr. Lane Roberts will speak.

NATIONAL INSTITUTE FOR THE DEAF.—Two lectures entitled the Wonders of Hearing and Facts on Deafness are to be given at 8 P.M. on Tuesday, Dec. 4th and 11th, at the Eustace Miles Restaurant, 40, Chandos-street, London, W., by Mr. C. M. R. Balbi, A.M.I.E.E., consulting electrical adviser to the Institute. Seats will be reserved for those who send a stamped addressed envelope to the Secretary at 2, Bloomsbury-street, W.C. 1, and unreserved seats will be open to the public.

POST-GRADUATE COURSE OF LECTURES ON CANCER. A series of four lectures will be held at the Medical School, Leeds, at 3.30 P.M. on Nov. 28th, Jan. 9th, Feb. 13th, and March 13th. The first will be on Cancer of the Breast, by Prof. A. H. Burgess; the second on Lead in the Treatment of Cancer, by Prof. W. Blair Bell; the third on the Lessons of the Recent Researches in Cancer, by Dr. A. Leitch; and the fourth on Cancer and the General Practitioner, by Mr. Cecil Rowntree. The lectures, the first three of which are to be illustrated by lantern slides, will be free to members of the profession.

ALLIANCE LODGE: Installation and Banquet.—The M.W. the Pro Grand Master, the Right Hon. Lord Amthill, was present on Nov. 14th at the Installation Meeting of the Alliance Lodge, No. 1827, which celebrated the jubilee of the Lodge. Some 80 brethren, including a considerable number of grand officers, and many distinguished in the craft and medical profession, attended at the Café Royal in the afternoon, when W. Bro. H. Moreland McCrea, M.D., opened the Lodge. The M.W. the Pro Grand Master Lord Amthill, assisted by the retiring Master, installed W. Bro. Ernest Clarke, F.R.C.S., P.M., P.G.D., as Master for the ensuing year, and subsequently delivered the addresses. The W.M. invested the following officers: I.P.M., W. Bro. H. Moreland McCrea; S.W., W. Bro. R. E. Sare; J.V., W. Bro. H. W. Carson, F.R.C.S.; Treasurer, W. Bro. J. S. Cotman, F.C.A., P.M., F.A.G.D.C.; Secretary, W. Bro. C. O. Hooper, F.C.A., P.M.; D.C., W. Bro. A. J. Clark, B.A., P.M.; S.D., W. Bro. B. Stenham, LL.B.; J.D., W. Bro. F. G. H. Holt; Organist, W. Bro. W. Sparks, P.M., P.G.D.; I.G., W. Bro. V. C. Dunfee; Stewards, W. Bro. Sir Holburt Waring, F.R.C.S., P.M., L.R., W. Bro. M. A. Nicholas, P.M.; and Tyler, W. Bro. T. Davis. The M.W. the Pro Grand Master was elected to honorary membership of the Lodge. The banquet was held at the Café Royal in the evening.

MEDICO-LEGAL SOCIETY.—The annual dinner of this Society will be held at the Holborn Restaurant, London, on Friday, Dec. 14th, at 7 for 7.15 P.M. Sir William Willcox, the President, will preside.

BRITISH DENTAL HOSPITAL.—The annual meeting will be held at 23, Russell-square, London, W.C., on Nov. 29th, at 8 P.M. Sir Harry Baldwin, the President, will take the chair, and Dr. Leonard Williams will speak on the Arch of the Buccal Building.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—A meeting will be held on Nov. 28th at St. John's Hospital, 49, Leicester-square, London, W.C., at 4.15 P.M. Clinical cases will be shown, and at 5 P.M. Dr. S. P. Bedson will read a paper entitled Observations on the Nature of Filtrable Viruses and their Bearing on the Ætiology of Herpes and Allied Conditions.

COLCHESTER HOSPITAL.—The accommodation for nurses at this hospital is so inadequate that some of them have to sleep three in a room. It has therefore been decided to extend the nurses' home at a cost of £30,000. The hospital serves 50 or 60 villages, some of which are making themselves responsible for the cost of a room in the new building.

PARAFFIN WAX IN BEEF DRIPPING.—On Nov. 15th, at Birkenhead police-court, a firm of manufacturers was fined £10 and £1 11s. 6d. costs for consigning a quantity of beef dripping which contained 8.4 per cent. of paraffin wax to a stallholder in the Birkenhead Market. Mr. H. E. Davies, public analyst, had stated that the paraffin wax was not only an adulterant, but might set up indigestion in anyone consuming the dripping.

HULL INFIRMARY EXTENSIONS.—Princess Mary, on Nov. 13th, laid the foundation-stone of the Sutton-on-Hull Annexe to the Royal Infirmary, Hull. The annexe is eventually to be enlarged to form an auxiliary hospital of 100 beds built on a site given by Mr. P. B. Reckitt, of Hull, and the Princess also declared open an extension of the out-patients' department of the infirmary, which has cost £10,000.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—Lectures and practical courses of instruction for the first part of this diploma will be held at the Maudsley Hospital, beginning on Jan. 8th, 1929. Lectures will be given on physiology, physiological psychology, biochemistry, anatomy and psychology, by Dr. F. Golla, Mr. S. A. Mann, Prof. G. Elliot Smith, and Dr. Henry Devine; and in addition four lectures on psychological mechanisms will be given by Dr. Edward Mapother.

A course for the second part of the diploma will be held from March to May inclusive. Inquiries should be addressed to the Director of the Central Pathological Laboratory, Maudsley Hospital, Denmark-hill, London, S.E.5.

DARENTH TRAINING COLONY, DARTFORD.—The Metropolitan Asylums Board has approved of the erection of a new nurses' home at a cost of over £40,000. The Mental Hospitals Committee reported that the cubicles on the top floor accommodating 46 of the female staff are dangerous in case of fire; that the nurses' sleeping quarters were scattered over the colony; and that some nurses had to use patients' baths in large bathrooms through which other nurses have to pass while bathing is in progress.

DONATIONS AND BEQUESTS.—The late Colonel D. Lewis, J.P., of Swansea, left, among other bequests, £10,000 to Gorseinon Hospital, £3000 to Swansea General and Eye Hospital, £500 each to Swansea General and South Wales Institution for the Blind, the Royal Cambrian Institution for the Deaf and Dumb, Swansea, and Swansea Orphan Home for Girls. The late Mr. T. A. Fisher, of Northampton, left, among other bequests, £500 to Northampton General Hospital for endowing a bed, and on his wife's death £2000 to Northampton and County Crippled Children's Fund, £500 to Northampton General Hospital, £300 to the Northampton and County Association for Promoting the General Welfare of the Blind, £300 to Victoria Nursing Home, Northampton, and the ultimate residue of the property equally between Dr. Barnardo's Homes and Moorfields Eye Hospital, London. By will the late Dame Grace Revere Osler, widow of the late Sir William Osler, left £10,000 to the McGill College, Montreal, Canada, for the upkeep of the Osler Library; £5000 to the Jefferson Medical College, Philadelphia, United States, for the establishment of a Lectureship in Surgery, in memory of Dr. Samuel W. Gross, her first husband; £2000 to the Tudor and Stuart Club or Library of the Johns Hopkins University, Baltimore, United States; £2000 to the Radcliffe Infirmary, Oxford, for the Osler Pavilion; £600 to the Gross Library at the College of Physicians, Philadelphia; £200 each to the Acland Home, Oxford, and the District Nurses' Association, Oxford.

ALVARENGA PRIZE.—The College of Physicians of Philadelphia announces that the next award of this prize, amounting to about \$300, will be made on July 14th, 1929. An essay intended for competition may be upon any subject in medicine, but must not have previously appeared in print, or been presented elsewhere in competition for a prize. Essays must be received on or before May 1st, 1929, by the secretary of the College at 19, South-22d-street, Philadelphia, Pa., U.S.A., from whom further particulars may be obtained.

The Alvarenga prize for 1928 has been awarded to Dr. J. R. Paul and Dr. W. U. McClenahan, Philadelphia, for the essay entitled *A Pathological Study of the Pleural and Pulmonary Lesions in Rheumatic Fever*.

PUBLIC HEALTH CONGRESS DINNER.—On Nov. 20th Sir Frederick Willis presided at a banquet at the Savoy Hotel. The Rt. Hon. H. P. Macmillan, proposing the toast "Parliament," defended the parliamentary system of legislature, despite its delays and exasperations, and paid a tribute to the loyal work done in Committee. He thought it a mistake to have too many professional men in Parliament; the duty of Parliament was to be constructive, and professional men were apt to be destructive and critical. Adequate representation of the medical profession, however, was essential. Dr. A. Vernon Davies responded, and described the sorrows of a Member's lot. "The Public Health Services" was proposed by Sir Henry Keith, who criticised the proposed rating reforms, which, he thought, would be disadvantageous to many public health services. The toast was acknowledged by Dr. W. M. Willoughby, who said that in the English people there was a genius for or an inculcated habit of health, and they had carried the public health idea throughout the world. Sir Edmund Barnard proposed the health of the chairman, who described the origin of the Congress and its object in bringing together the practical and scientific side of public health work (see p. 1079). He related his part in elevating the Local Government Board from a junior branch to one of the most important departments of State. The Congress was designed to enhance still further the importance of the public health administration. It was hoped to found a Chair of Public Health at a university. Progress could only be made by constant research, constant application of research, and the devotion of Government officials. He hoped the Congress would become a biennial institution, and proposed the health of the secretaries. Mr. Warner Terry replied.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—Dr. J. Howard-Jones, the President, took the chair at the annual dinner of this Society, held at the Piccadilly Hotel London, on Nov. 15th. The toast of the Society was proposed by Mr. H. P. Macmillan, K.C., late chairman of the Royal Commission on Lunacy and Mental Disorder, who spoke of the debt owed by the public to their medical officers. He believed that the health of the people had been enormously benefited by recent legislation and its administration by members of the Society. There was a certain risk of too much interference with the lives of individuals, and the aim, he thought, should be not to do things for people but to teach them to do things for themselves. An immense amount of educative work was being done and was being reflected in the homes of the population. Dr. Howard-Jones, in responding, spoke of the vital statistics of the Society, which was now in its period of growth. Its 13 branches extended to India and the Malay States, but there was as yet no branch in Ireland. Preventive medicine—theoretically the greatest department of medicine—was now invading the other departments; yet the cost of the work controlled by M.O.H.'s throughout the country worked out at only 6s. 3d. per head of the population per annum. Dr. Howard-Jones believed that the interchange of medical officers was probably doing more to promote international goodwill than any other activity of the League of Nations. He concluded by speaking of the Society's secretary, Mr. G. S. Elliston, who had won the admiration and respect of every member. Dr. Charles Porter proposed the toasts of the Guests in a singularly happy speech devoted chiefly to their recreations. He apparently believed that public men should have no time for recreation. In reply, Dr. Haden Guest pleaded for more scientific thought in politics and public affairs. Over questions of public health there was seldom great excitement, the reason being that they had been properly weighed and analysed. There ought to be a conquest of other political questions by quiet-minded people. As we approached the general election there was less and less sober consideration of national problems, yet they needed as careful examination as the problems of local administration or science. He wished that there could be at least 50 medical M.P.'s and three medical Ministers. Dr. H. B. Brackenbury, chairman of Council of the British Medical Association, said that the distinction between curative and preventive medicine was becoming less and less real. Practitioners were now called

upon to do both preventive and curative work. Mr. Henry Lesser, President of the National Association of Insurance Committees, referred to the need of cooperation between insurance organisations and the M.O.H. Councillor Walter Griffiths, Mayor of Newport, spoke warmly of the admirable work of the President for the town of Newport and for the mercantile marine, and Prof. H. Kerr proposed Dr. Howard-Jones's health. After this had been drunk with musical honours, the President briefly replied.

During the evening Mr. Charles Pond entertained the company with great success.

CONGRESS OF RADIOLOGY DINNER.—In the course of the Congress arranged jointly by the British Institute of Radiology and the Röntgen Society (reported in another column) a dinner was held at the Trocadero Restaurant, at which the President, Dr. G. W. C. Kaye, occupied the chair. After the loyal toast a silent tribute was paid to the memory of Dr. Robert Knox. Mr. Cuthbert Andrews proposing "The Institute," coupled with the name of the chairman, recalled the fact that while the combined society was only a year old, difficulties had already been overcome, and although the organisation and working were still far from perfect, with the active coöperation of every member the Institute was on the way to becoming a powerful body whose influence would be international. The President in his reply referred to the work of Bédère, J. J. Thomson and Rutherford to whom radiology was so deeply in debt, and recorded his appreciation of the efforts of the manufacturers to make the November meeting and exhibition a success. The forthcoming joint meeting of the Institute of Electrical Engineers and the British Institute of Radiology would, he felt sure, bring much benefit to radiology, and he terminated his remarks by assuring those present that the Institute would grow into a great and powerful body. Dr. A. L. Rowden, Vice-President, proposed "The Guests," associating with the toast the names of Sir Thomas Horder, Mr. H. T. Tizard, Lieut.-Colonel K. Edgcombe, President of the Institute of Electrical Engineers, Mr. W. Sampson Handley, Mr. A. J. Walton, Dr. J. E. A. Lynham, and Sir Humphry Rolleston, Past President of the Institute. Sir Thomas Horder, in reply, referred to his long association with the late Dr. Knox and other pioneers. In view of the turn given by the press to certain remarks of his made at the Congress he took pains to assure his listeners that he found the assistance given by radiology in clinical work second to none. Mr. Tizard registered his appreciation of the close contact necessary between science and medicine, well exemplified in their combined society. Colonel Edgcombe felicitated the society on the good work done at the recent international congress where the British view of the protection question had been adopted in its original form. Sir Humphry Rolleston proposed "The President," and Dr. Kaye, in reply, thanked the office-bearers, not forgetting the dinner committee, for their timely interest and assistance, and in his turn proposed "The Past President." Auld Lang Syne was heartily sung in conclusion.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
MONDAY, Nov. 26th.—8 P.M., ODONTOLOGY. Paper: Dr. E. W. Fish: Dead Tracts in Dentine. Casual Communication: Sir Frank Colyer: Irregularities of the Teeth in *Erythrocebus* (Patas Monkey).
TUESDAY.—5 P.M., MEDICINE. Clinical Meeting at University College Hospital, Gower-street. Cases: Dr. Poynton: Pernicious Anemia in a Young Girl. Dr. Goodhart: Two Cases of Splenomegalia Familial. Jaundice with Severe Crises of Anemia. Dr. Elliott: Biliary Cirrhosis and Hypercholesterinæmia. Blood Picture and Unusual of Pernicious. Renal Radiogram. Dr. McNeely: Splenectomy for Alcoholic Osteitis. Dr. W. A. Harris: Paget's Injury to Hip. Radiotherapy in Paroxysmal Hemiplegia. Dr. K. E. Harris: Hemiplegia and High Blood Pressure. Familial Polycystic Kidneys.
WEDNESDAY. MEDICINE. Paper: Dr. William G. Savage: Unsolved Problems of Salmonella Food Poisoning.
THURSDAY.—8.30 P.M., Sir William Bragg: Faraday's Diary, with illustrations and exhibits. Lloyd Roberts. Lecture. (Admission by ticket only.)

ROYAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
 MONDAY, Nov. 26th.—8 P.M.: Clinical Evening.
 L INSTITUTE, Albemarle-street, W.
 THURSDAY, Nov. 29th.—5.15 P.M., Dr. E. D. Adrian, F.R.S.: The Mechanism of the Nerves.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, London,
 MONDAY, Nov. 26th.—8 P.M., Dr. Franklin Kidd, D.Sc.: Biology and Refrigeration. (Lecture III.)

ROYAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.
 FRIDAY, Nov. 30th.—8.30 P.M., General Meeting. A paper will be read by the President, Dr. F. J. H. Coutts, on Venereal Diseases from the Epidemiological Point of View. A discussion will follow.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL SOCIETY OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Nov. 26th, to SATURDAY, Dec. 1st.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Lecture by Dr. Donald Paterson: Some Problems in Infant Feeding, on Mon., at 5 P.M. Mr. Victor Bonney, at the Medical Society, on Gynaecological Talk, Wed., 11 A.M.—CENTRAL LONDON OPHTHALMIC HOSPITAL, Judd-street, W.C. Thurs., at 4 P.M. Demonstration by Mr. Cunningham.—PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N. Mon., at 2.30 P.M. Dr. A. J. Whiting (Ward Round).—WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Wed., at 4 P.M. Demonstration by Dr. Philip Manson-Bahr on Prevention and Treatment of Malaria. The above are free.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Special course in Medicine, Surgery, and Gynaecology.—ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, Broad-street, Holborn, W.C. Special Course.—ST. PETER'S HOSPITAL, Henrietta-street, W.C. Special Course in Urology.—WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck-street, W. At 5 P.M. Lecture-demonstrations, illustrated by cases daily.—LONDON LOCK HOSPITAL, Dean-street, W. Clinical instruction in O.P. Department. Further information from the Secretary.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Nov. 26th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards 2 P.M., Mr. Simmonds: Surgical Out-patients.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases (demonstration). 2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose and Ear Department.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards. 4.30 P.M., Dr. Carter Braine: X Ray Therapy.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Ironside: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—9 A.M., Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.

Daily 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anaesthetic Course.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.
 MONDAY, Nov. 26th.—4.15 P.M., Dr. Charles Singer: Plague. Second lecture on the History of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Nov. 26th.—2.30 to 5 P.M.: Medical, Surgical, and Gynaecological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M. Surgical, Medical, and Children's Diseases Clinics. Operations.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Nov. 27th.—5 P.M., Dr. A. Whitfield: Tuberculosis Cutis (2).

THURSDAY.—5 P.M.: Dr. H. Haldin-Davis: Acne. Rosacea.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Nov. 29th.—4 P.M., Dr. Pearson: Constipation.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Nov. 30th.—4 P.M., Mr. Watkyn-Thomas: Two Cases of Brain Abscess.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.
 TUESDAY, Nov. 27th.—3.15 P.M. (at the Royal Chest Hospital), Mr. S. J. F. Webb: The Need of Removal or Conservation of Teeth in Relation to Systemic Disease

ST. PAUL'S HOSPITAL POST-GRADUATE COURSE, Endell-street, W.C.

THURSDAY, Nov. 29th.—4.30 P.M., Mr. Kenneth Walker: The Enlarged Prostate.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

WEDNESDAY, Nov. 28th.—4 P.M., Dr. H. M. Vernon: The Fatigue of Heavy Industrial Work, and its Influence on Health and on the Duration of Working Life. (With lantern illustrations.)

JOINT TUBERCULOSIS COUNCIL POST-GRADUATE COURSES.

MONDAY, Nov. 26th, to SATURDAY, Dec. 1st.—A Post-Graduate Course of Lectures and Demonstrations on the Pathology of Tuberculosis and Allied Chest Diseases will be held at the City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E. Further particulars from Dr. W. Brand, The Larches, Farnham Royal, Bucks.

CHADWICK PUBLIC LECTURES.

MONDAY, Nov. 26th.—7.30 P.M. (in the University College of the South West, Exeter), Dr. P. B. Ballard: Open Air Schools.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Nov. 27th.—4.15 P.M., Mr. D. L. Sewell: Foreign Bodies in Food and Air Passages.

FRIDAY.—4.15 P.M., Dr. G. E. Birkett: General Principles of Radium Therapy.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.
 FRIDAY, Nov. 30th.—3.30 P.M., Mr. Cu: Surgical Cases.

Appointments.

ADAM, J. N., M.B., Ch.B. Edin., F.R.C.S. Edin., has been appointed Hon. Surgeon to the Chester Royal Infirmary.
 ANGUS, W. B. G., M.D. Camb., F.R.C.S. Edin., a Medical Referee under the Workmen's Compensation Act for the District of Stirling, Dumbarton and Clackmannan.
 GLAISTER, J., jun., M.D., Ch.B. Glas., Professor of Forensic Medicine in the University of Cairo and Medico-legal Adviser to the Egyptian Government and Courts.
 LEASE, R. L., M.B., Ch.B. Glas., D.P.H., Assistant Tuberculosis Officer for the Eastern Division of the County of Fife.
 LISTER, A. R., M.B., B.Chir. Camb., F.R.C.S. Eng., Assistant Surgeon, York County Hospital.
 LORD, J. R., C.B.E., M.D., C.M. Edin., Hon. Lecturer in Clinical Psychiatry, London School of Medicine for Women.
 O'DOHERTY, M. I., M.B., B.Ch. N.U.I., Medical Officer of Nobber, Meath.
 WILSON, W. ETHERINGTON, F.R.C.S. Eng., Hon. Consulting Surgeon to Totnes and District Cottage Hospital, Devon.
 Certifying Surgeons under the Factory and Workshop Acts: BLORE, W. R., M.B., B.S. Lond., M.B., Ch.B. Manch. (Halesowen, Worcester); and PARGETER, H. A. A., M.B., B.Chir. Camb. (Dunstable).

Vacancies.

Radiographer.
Rochester, St. Bartholomew's Hospital.—Res. Surg. O. At rate of £225.
Royal Waterloo Hospital for Children, &c., Waterloo-road, S.E.—Pathologist. £250.
St. Albans and Mid-Herts Hospital and Dispensary.—Res. H.S. £150.
St. Bartholomew's Hospital, E.C.—Asst. Surg. to Throat Dept.
St. Mary (Islington) Infirmary, Highgate Hill, N.—Asst. M.O. At rate of £350.
St. Marylebone Hospital, Ladbroke-grove, W.—Third Asst. M.O. £300.
St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—Clin. Assts.
Salisbury, General Infirmary.—Pathologist. £1000.
Shanghai Municipal Public Health Dept.—Asst. Radiologist. Also Asst. Pathologist. 700 and 650 taels per month respectively.
Sheffield, Royal Infirmary.—Jun. Aural and Ophthalmic H.S. At rate of £80.
Sheffield University.—Sen. Demonstratorship in Anatomy. £400.
Southampton, Free Eye Hospital.—H.S. £150.
South-Eastern Hospital for Children, Sydenham.—Hon. Asst. Phys.
South London Hospital for Women, South Side, Clapham Common, S.W.—Clin. Assts.
Surrey County Council, Kingston-upon-Thames.—Asst. M.O. £800.
Taunton and Somerset Hospital.—Jun. House M.O. At rate of £100.
University College Hospital, Gower-street, W.C.—Ophth. Reg. £50.
West London Hospital, Hammersmith-road, W.—H.P., H.S. Also Aural and Ophth. H.S. Each at rate of £100.
York County Hospital.—H.P. £150.

Births, Marriages, and Deaths.

BIRTHS.

HECKELS.—On Nov. 15th, at Ashley-road, Epsom, the wife of Graham W. Heckels, M.B., B.S. Lond., of a daughter.

MARRIAGES.

ATKINSON—HUNTER.—On Nov. 15th, at Victoria-road, Queen's Park, Glasgow, Surgeon-Captain Edward Leicester Atkinson, D.S.O., A.M., F.R.C.S., to Mary Flint, only daughter of the late Mr. and Mrs. John Hunter, Queen's Park, Glasgow.

MACPHERSON—CLAYDON.—On Oct. 22nd, at Lahore, India, Norman Stewart Macpherson, F.R.C.S., to Thelma, fifth daughter of Canon and Mrs. Claydon, Sydney, N.S.W.

DEATHS.

BARNARD.—On Nov. 17th, John Henry Barnard, O.B.E., M.D., M.R.C.S., aged 75.

COKER.—On Nov. 16th, at Chamberlain-street, Wells, Somerset, Owen Cole Coker, L.R.C.P. Lond., late of Uxbridge-road, W., and of The Towers, Bigbury-on-Sea.

DASHWOOD.—On Nov. 14th, at Rodney-road, S.E., Charles Ewart Dashwood, M.R.C.S., L.R.C.P., late of Taormina, Sicily, aged 58.

NOAD.—On Nov. 14th, at Hove, Ernest Noad, M.R.C.S. Eng., L.R.C.P. Edin.

RACKHAM.—On Nov. 15th, at North Elmham, Norfolk, Arthur Richard Rackham, M.R.C.S., L.R.C.P.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

DISEASES OF THE EYE IN RELATION TO GENERAL MEDICINE.*

BY GLADYS M. WAUCHOPE, M.D., M.R.C.P. LOND.,
 ASSISTANT PHYSICIAN TO THE NEW SUSSEX HOSPITAL FOR
 WOMEN AND CHILDREN, BRIGHTON.

Oculi indices animi sunt.—That the eyes are the informers of the mind is true in medicine both of what we see with our own eyes and of what we observe in our patients' eyes. To begin with, we learn much from the way in which the patient looks at us. A shifting nervous eye may put us on the track of some mental trouble aggravating or indeed causing symptoms. Exophthalmos, squints, unequal or unusually small pupils may be valuable indications. The general appearance of the eye is often characteristic—for instance, the almond-shaped eyes of Mongolian idiocy and the half-closed eyes of tuberculous meningitis—while a large, bright eye with a good deal of the white showing is associated with hysteria.

The eye may hoist a danger-signal that brings a patient to his doctor. A healthy person suddenly "sees double." This may indicate a central lesion and be the first symptom of encephalitis lethargica, tabes dorsalis, or disseminated sclerosis, or the double vision may be due to a peripheral lesion and may indicate basal meningitis, meningo-vascular syphilis, neuritis due to poisons such as lead and alcohol, or endogenous toxic conditions such as diabetes, where the sixth nerve is particularly liable to be affected. (Maitland Ramsay.)

Sudden loss or defect of vision is another alarming symptom and may lead to the discovery of various conditions, many of them purely local, while others are the visible signs of a general disease. Among the latter are: 1. Retinitis, diabetic or albuminuric. 2. Retinal hemorrhages, associated with advanced arterio-sclerosis. 3. Embolus of the central artery of the retina or thrombosis of the vein leads to the loss of sight in one eye, and may be associated with heart disease, syphilis, arterio-sclerosis, &c. 4. Papilloedema due to intracranial tumour, especially of the pituitary, when bitemporal hemianopia is also present. 5. Optic neuritis and optic atrophy, in tabes and general paralysis of the insane, and occasionally in disseminated sclerosis and acute myelitis. 6. Toxic amblyopia, an interstitial neuritis of the optic nerve brought on by the excessive consumption of tobacco and alcohol. 7. Endogenous toxic amblyopia or amaurosis, diabetic or uræmic; uræmia, indeed, is said to be the most common cause of sudden blindness. 8. Night-blindness, which may be an early symptom of adult scurvy. 9. Hysteria, where the eye itself is normal.

The Eye in Diagnosis.

The eye may be a "sign-post" pointing to an otherwise doubtful conclusion: 1. A coincident iritis in a case of multiple arthritis incriminates the gonococcus. 2. Interstitial keratitis in the absence of typical (or any) teeth indicates congenital syphilis. 3. Unequal or fixed and contracted pupils in a case of mental derangement point to general paralysis of the insane. 4. "The glittering eye" of early Graves's disease suggests the diagnosis, before exophthalmos or other definite signs appear. 5. A hemorrhage into the orbit may suggest scurvy. 6. Exophthalmos in a child with an obscure abdominal tumour indicates Hutchinson's renal sarcoma (neuroblastoma). 7. Exophthalmos may point to chloroma and lead to the discovery of leukemia. 8. The greenish corneal pigment identifies progressive lenticular degeneration. 9. How often does the general practitioner look at weepy red eyes and say "I think this child is sickening for measles"? 10. Oedema of the eyelids may occur in chronic arsenical poisoning.

In other diagnostic problems the eyes may give the "casting vote": 1. Examination of the optic disc may decide between cerebral tumour and meningitis. 2. Nyctagmus establishes a diagnosis of disseminated sclerosis and puts hysteria out of court. 3. A tuberculous nodule in the chorioid distinguishes the two common forms of meningitis in children. 4. Argyll Robertson pupils decide for tabes against a pure spinal cord lesion.

In the localisation of the site of a lesion the eye may be invaluable. Hemianopia places the lesion in a particular part of the optic tract; pin-point pupils indicate the pons; dilatation of one pupil shows that there is irritation of the cervical sympathetic. Loewy's midriatic test for pancreatic insufficiency depends on pupil reactions.

* A paper read before the Medical Women's International Association at Bologna.

† Word obliterated.

RESEARCH IN MENTAL DISEASE.

THE annual report of the Joint Board of Research for Mental Diseases of the city and University of Birmingham records a great deal of routine work—3861 specimens in all—and 45 autopsies, as well as the continuation and elaboration of the research of past years. The investigation of the fat-lipoid-cholesterol ratios in adrenals and gonads is ready for publication, and further experiments on basal metabolism have been carried out. A special technique has been developed for investigating the bacteriology of the nasal sinuses, and an attempt has been made to correlate endocrine disturbances with septic conditions in the region of the pituitary gland. One case clearly showed the passage of organisms from the sinus membrane into bone, dura mater, and pituitary. The permeability quotient has been investigated with reference to changes which might follow non-protein and arsenical therapy in general paralysis.

A NEW POCKET HEAD LAMP.

THE Holborn Surgical Instrument Company, Ltd., 26, Thavies-inn, Holborn-circus, London, W.C., have placed on the market a new pocket head lamp which is contained, complete with battery, when not in use, in a little leatherette case measuring $5\frac{1}{2} \times 3 \times 1\frac{1}{2}$ inches. In use the special filament lamp is connected to the battery by a length of flex, a lens cap concentrating the light on one spot. The lamp is fitted to an elastic head band, and the apparatus makes a very compact and convenient means for examination purposes. The lamp is switched on and off by means of the ball and spring contact by which it is hinged to the forehead piece. The price of the apparatus is moderate, and spare lamps and batteries can easily be obtained.

CONCENTRATED DIPHTHERIA ANTITOXIN.

British Drug Houses, Ltd. (10-30, Graham-street, City-road, London, N.1.) are now prepared to supply a super-concentrated and refined diphtheria antitoxin (D.S.I.) containing 2500 Ehrlich units per c.cm. with a protein content not exceeding that of natural serum. This enhanced therapeutic action has therefore been obtained without any increased risk of serum sickness, and without impairment of the reaction velocity of the antitoxin. The D.S.I. brand contains two and a half to five times the number of antitoxin units contained in an equal volume of ordinary natural serum. Its use is recommended in cases of diphtheria where time is of vital importance. It is supplied in rubber-capped phials containing 10,000 or 20,000 units. Kept in a cool and dark place, the serum is believed to retain its antitoxic potency for at least two years.

THE RADIOGRAPHER'S PONS ASINORUM.

Dr. W. Cotton, who has written extensively on X ray technique, sends us a reprint of a paper which he read at the recent Congress of Radiology at Stockholm. In this paper he dealt pictorially with perspective in relation to X ray interpretation, and emphasised particularly what he describes as the "pons asinorum radiographicus." Starting from the axiom that perspective deals with correct picture-making and viewing by straight lines radiating through the "original station point" (OSP), including images formed on any picture plane (PP) by X rays, photograph or drawing, he remarks that in radiography the OSP is the centre of emission of the focus tube and the only proper centre for the interpreter's eye, looking towards the objects portrayed. The pons asinorum he states thus: (1) The remote side of the PP is not a picture from their remote side of the parts depicted. (2) The remote side of any picture is a picture of the parts reversed as in a plane mirror. (3) A fluorescent screen in action is not a transparent window pane, but only a translucent window-blind viewed from the street, with the contents of a locked antechamber shadowed thereon from the keyhole.

MICROSCOPES.

THE sectional catalogue (List E 7) issued by Messrs. Reichert (Vienna) describes very fully the range of instruments and accessories manufactured by them. The microscopes range from low-power dissecting magnifiers of various types to large binocular instruments and specialised forms for mineralogical and biological work. Sectional diagrams illustrate the optical and mechanical details of many of the instruments, and tables are given showing the magnification produced by various combinations of objective and eyepiece. In the photomicrographic section weight and bulk have been economised to a high degree without sacrifice of the essential rigidity. Several of the cameras shown can be adjusted for copying, slide-making, and photographing small objects without the use of the microscope. The advance in lightness and adjustability is to be seen in the epidiascope described, which is smaller than many of the standard forms and can, amongst its other adjustments, be used to project a cinema film.

PRESERVATIVES IN FOOD.

THE International Office of Public Hygiene at Paris has sent out a questionnaire to all countries relating to the preservatives and colouring matter in food permitted for home use, for export, and for those at sea. Replies received from the Polish Republic and from Japan have been published as a supplement to the monthly *Bulletin* for August issued by the International Office. In regard to Poland the replies are no longer valid, since in July, 1928, a new law came into effect based on the practice of the Austrian and Prussian provinces. In Japan the only legal preservative is salicylic acid, which is allowed in "saké," the national beverage, to the amount of 208 mgm. per litre. The tolerated amounts of preservatives seem generally to be higher in our own country than in the other countries mentioned. On the other hand, we treat the whole world alike; the regulations made by the Minister of Health appear to apply to all articles manufactured for sale or sold, whatever their destination. The Japanese restrictions also apply to all alimentary products which are manufactured in Japan, whether they are destined for consumption in the country itself or for exportation. Poland specifically excluded from the restrictions "alimentary products destined to be exported or employed as provisions aboard ships." It is difficult to gather whether this exemption was due to a disregard for the welfare of the seafaring man and the foreigner or to a deliberate choice of the supposed lesser of two evils on a long voyage—preservatives or putridity. It may be significant that the two island States, England and Japan, apply the same restrictions to foods for the sailor as to those for the landsman. Even in these days of hustle on the sea the crew of a tramp steamer get limited opportunities of enjoying fresh food.

THE FEEDING OF YOUNG CHILDREN.

THE object of a little book¹ which reaches us from America is to help those who have the task of arranging meals for children between the ages of 2 and 6 to observe a just balance between the various food elements, and to ensure the use of a dietary which may be relied upon to produce normal development. Menus are supplied for every month in the year, to be used as a working basis for family meals, and a whole section is devoted to preparation and cooking of food with recipes embodying the articles recommended. The book bears evidence of its nationality, and some modification will be needed in this country. The prudent English mother would hesitate to include fresh peaches and pineapples in the daily fare, and "white squash," "cambric tea," and "pettijohn" must convey more to the American than to the English public. These, however, are details, and the conscientious housewife will be grateful to find in the pages of this volume much thinking and planning done for her, and will welcome Dr. Richard M. Smith's assurance in his foreword that "any mother can safely use this book and be reasonably sure that her child's requirements in quantity and kind of food will be adequately met." Appendices contain lists of foods according to their vitamin content, and their protein and mineral relation to caloric values.

¹ Feeding the Child from Two to Six. By Mary Frances Hartley Barnes. New York: The Macmillan Company. 1928. Pp. 206. 10s. 6d.

GIFT FOR THE PURCHASE OF RADIUM.—The patient of a member of the staff of St. Bartholomew's Hospital, who has been successfully treated with radium, has given £14,000 anonymously to the hospital towards the extension of facilities for this treatment. The money will be used to purchase more radium and to instal an emanation plant.

TUNBRIDGE WELLS WATER-SUPPLY.—Tunbridge Wells Corporation is seeking Parliamentary powers to purchase compulsorily about 805 acres of land between Matfield Green and Pembury with a view of securing control of the town's chief source of water-supply. A sum of £70,000 is involved in the scheme, and the proposal was accepted by the corporation without any discussion.

NEW HOSPITAL AT ILFORD.—The Lord Mayor of London and the chairman of the London County Council have been asked to serve the rapidly growing population of Ilford, an area which includes the Council's Becontree housing estate. It is hoped that the Ilford Emergency Hospital may form the nucleus for a voluntary general hospital of 300 or 400 beds. King Edward's Fund have promised a first contribution of £10,000 provided that at least as much is forthcoming from other sources. The County Council is providing a similar sum.

An Address

ON

CHRONIC SPASMODIC AFFECTIONS
OF THE COLON

AND THE DISEASES WHICH THEY SIMULATE.

*Delivered before the Sheffield Medical Society on
Nov. 29th, 1928,*By JOHN A. RYLE, M.D., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO GUY'S HOSPITAL.

OF the problems which confront the physician and the surgeon few are more troublesome than those which require the interpretation of chronic or recurring abdominal pain. Frequently the diagnosis must be attempted in the absence of any conspicuous objective sign, and, with symptoms for guidance, a decision must be made between "organic" and "functional," or, what is more serious for the patient and more exacting in clinical judgment, between a surgical and medical plan of relief. Modern investigations do not always provide the clue. Discussions which serve, in however small a degree, to illuminate this dark field of diagnosis are therefore to be encouraged, and we should be very ready to share our observations and our difficulties.

However great the triumphs of surgery may be in the acute abdominal catastrophes and in certain forms of chronic abdominal disease, none of us can feel content with the present position of abdominal surgery as a whole. We still see too many scarred abdomens with persistence of symptoms, too many "re-operations" and operations undertaken for pain, and it is disturbing to reflect upon the hours which must be lost annually to surgeons and their patients in the conduct of unrewarded appendicectomies, a considerable proportion of which have doubtless been advised by physicians. I would suggest that our shortcomings are less in respect of technique than of diagnosis, employing the term in its fullest sense of "thorough knowledge" of our cases.

Such remarks as I shall have to make are to be regarded as a slender contribution to the study of a not uncommon abdominal disorder which is characterised by frequent and prolonged discomfort, or troublesome and even severe pain; which is unassociated with any demonstrable organic change in the abdominal viscera; which sometimes simulates important organic disease; and for which consequently operations and explorations are performed.

The condition is variously referred to in the literature as *spastic constipation*, *chronic colospasm*, *spastic colon*, and *tonic hardening of the colon*. For convenience I shall refer to it as *spastic colon*.

HISTORICAL.

In Chapter IV. of his "Constipation and Allied Intestinal Disorders" Hurst¹ gives a useful bibliography of the subject and a concise account of the aetiology and important clinical features of the malady. It was first described by John Howship,² surgeon to St. George's Infirmary, London, in 1830, in a small and very readable book entitled "Practical Remarks on the Discrimination and Successful Treatment of Spasmodic Stricture in the Colon considered as an occasional cause of Habitual Confinement of the Bowels." He recognised that the complaint was due to "a deficient freedom of relaxation in some part of the intestinal canal," and both as a diagnostic test and a therapeutic measure advocated gradual distension of the bowel with a large warm gruel enema. Cherchewsky,³ who was unfamiliar with this account, redescribed the condition in 1883. Fleiner⁴ wrote his first article on spastic constipation in 1893. In this country Hawkins⁵ wrote an admirably descriptive paper based on the study of

5492

35 cases of enterospasm in 1906, drawing particular attention to the frequent confusion of the disease with appendicitis. The subject has hitherto attracted more attention on the continent, but latterly there has been a revival of interest in England. Turner,⁶ from the surgeon's point of view, furnished an article to the Guy's Hospital Reports in 1924. Dr. G. Evans made it the subject of a communication to the Association of Physicians of Great Britain and Ireland in the present year. Stacey Wilson,⁷ who had previously discussed the physiology of the pain in this disorder, has recently summarised his own views and wide experience in a book entitled "Tonic Hardening of the Colon." In this he discusses clinical features and advances his own therapeutic beliefs, but attributes, in my opinion, too long a list of physical and mental disturbances to the direct agency of tonic hardening.

THE CLINICAL PICTURE OF SPASTIC COLON.

The descriptions which follow are based on an analysis of 50 cases interrogated and examined by myself. The series includes 39 cases of spastic colon unaccompanied by mucus excess in the stools and 11 cases of the condition usually called mucous-membranous colitis, or, better, mucous colic or mucous-membranous colic, for cytological examination of the stools and the sigmoidoscope reveal no signs of ulceration and little or no evidence of active inflammation of the mucosa. The cases were taken from my file consecutively and with no special selection, excepting that those in which there was an element of doubt or obvious coincidental disease were excluded. The proportion of "spastic colon" cases to cases of "mucous colic" is, I believe, representative. The more detailed consideration of aetiology, symptoms, and physical signs is preceded by an account of an individual case portraying the more important features.

CASE 1.—A middle-aged professional man, of lean type and nervous constitution and liable to migraine, first started to have right-sided abdominal pain some 16 years ago. At one time and another cholecystitis and appendicitis were diagnosed, and finally, after careful investigation, the appendix was removed. He still, however, has the right-sided pain, and at times can feel for himself a sausage-like lump in the right flank. The attacks arrive especially in spring and autumn, and are precipitated by cold, fatigue, and mental worry. In a hot bath the pain is eased and the tumour fades away. The patient and his brother are both unable to face a cold east wind without developing abdominal pain. The pain shows a tendency to appear 2½ hours after a meal. Examination revealed general right-sided tenderness, and on one occasion the cæcum or ascending colon became vaguely palpable. The descending colon was felt like a firm cord, and occasionally the transverse colon was also felt. There were no other signs of disease. The patient found that a good open-air holiday with exercise and mental rest was best calculated to bring relief.

ÆTIOLOGY OF SPASTIC COLON.

Sex Incidence.—In the present series of 50 cases there were 17 males and 33 females. Excluding the cases with mucous colic which, with rare exceptions, are confined to the female sex, there were 16 males and 23 females.

Age Incidence.—The youngest patient was aged 19, the oldest 78. The average age was 39.

Physical and Psychological Types.—Nineteen cases were specifically described in my notes as "lean," "thin," or "spare." "Wiry," "dark," "tall," and "pale" were other adjectives which occurred with conspicuous frequency. Twenty-seven cases were recorded as nervous, neurotic, worrying, or anxious. Migraine and asthma were entered against the patient or an immediate relative with sufficient frequency to suggest a more than coincidental association. The association with asthma is commented upon by Hawkins.⁵

Family History.—In addition to these associations and general references to "nervous stock," there were two examples in my series of two brothers both suffering from spastic colon.

The evidence for a constitutional or diathetic factor is thus fairly strong, and has, I think, usually been

remarked by those interested in the condition. Conversely I would suggest that it is extremely rare to meet with spastic colon in fair-haired, blue-eyed, healthy-complexioned types with placid dispositions or in robust individuals. In my own experience spastic colon is more common in private than in hospital practice. As Hawkins remarks, "Intestinal neuroses diminish in frequency as we descend the social scale."

Predisposing Illnesses and Intoxications.—*Dysentery*, as might be expected from the habit of irritability which it engenders in the bowel, may be followed by spastic colon, and this even for years after the active infection has subsided. Three cases occurred in my series. Hurst also refers to the influence of lead and tobacco, and to colonic spasm reflexly induced by gall-stones, ureteric calculus, or other irritative visceral lesions, or due to tabes dorsalis. It is very difficult to assess the part played by tobacco. I would suggest that it is rarely the sole or main factor. Most of my male patients were smokers, and four of them really excessive smokers. On the other hand, the majority of the women were non-smokers. Occasionally I have seen patients with spastic colon in association with other manifestations of tobacco excess, such as sweating, dizziness, and palpitation. Plumbism and such coincidental diseases as appendicitis, diverticulitis, gall-stones, and tabes were, so far as possible, excluded. The causal or contributory effect of *purgatives* must be given due prominence. Thirty of the cases were recorded as constipated, and of these the majority were taking laxatives or purgatives occasionally or habitually. It cannot be doubted that undue irritability of the neuro-muscular mechanism of the bowel is present in these cases, and that the majority of the popular purgatives, however mildly so, are irritants. Furthermore, not a few of the patients are well aware that their pain may be aggravated by brisk purgation.

Constipation.—How far constipation is to be regarded as a cause or a consequence of the spasm it is difficult to say, but, as already mentioned, it was present in 30 (60 per cent.) of the cases. Nevertheless it is important to recognise that pain and tonic hardening of the colon are consistent with regular and apparently normal bowel function. Attacks of "diarrhoea" are a constant feature in mucous colic. Diarrhoea, occasional or constant, was also recorded in seven cases of simple spastic colon. In some cases, both costive and otherwise, it is tempting to believe that a low grade colonic infection is at work, but we have no certain information on this point. The cases are not pyrexial.

FREQUENCY OF PREVIOUS APPENDICECTOMY.

In 18 (36 per cent.) of my cases the appendix had been removed. In one of these it was removed during a laparotomy which I myself advised (vide Case 3). In only three instances was it specifically noted that the appendicectomy was undertaken for acute appendicitis. In several instances the operation was undertaken for relief of pain not dissimilar from that for which relief was again sought. In one case there had been two further explorations. In other cases a diagnosis of "chronic appendicitis" had been suggested.

THE PATIENT'S SYMPTOMS.

The leading complaint is usually of discomfort or pain in the lower abdomen. The *discomforts* are variously described as a feeling of stagnation or "stoppage," as "a ball" or "a lump," or as a sensation "like a bar of lead"; the direction of this bar may actually correspond with some part of the large bowel, and the description is remarkable for the nicety with which it interprets the tonic rigidity present in the affected segment. The *pain* is usually a dull continuous ache, sometimes "gnawing" or "like a toothache," never rhythmical or gripping as in the colic of purgation, acute enteritis, or intestinal obstruction, and even in the severe cases unlike the relentless, immobilising pain of an acute inflammatory lesion. It varies in severity from something quite

trivial to an intensity—as will be described later—so severe as to simulate the major colic of a ureteric calculus, and to call for the administration of morphine. These severe cases are fortunately rare. Diagnosis even in the attack may be extremely difficult. In a case of average severity the pain is at times troublesome enough to interfere seriously with work or pleasure, although it is noteworthy that sleep is seldom lost on account of it. It is usually referred with accuracy to the part of the colon involved, and I must differ from Stacey Wilson¹ when he states that the distribution is segmental. A common gesture is the application of the palm of the right or left hand to the corresponding iliac fossa, when the proximal or distal portions are affected. In the case of the transverse colon the course of the pain is traced with a finger or shown with the ulnar border of the hand. For purposes of brevity I tabulated the caecum and ascending colon as "first part"; the transverse colon as "second part"; and the colon from the splenic flexure to the commencement of the rectum as "third part." Of the cases in which observations of the part affected were noted the first part was indicated in 26, the second in 14, and the third in 21. Rectal pain was also recorded in a few cases. Some patients could only describe a vague lower abdominal "stomach-ache." Variations in the situation of the pain are spontaneously described. Associated pyloric spasm and, in women, bladder discomfort and frequency are not rare. "Dead fingers" are a common complaint. With the pain there is often mental depression or irritability and physical inertia. Both onset and relief may be abrupt and occur for no apparent reason. The duration of the pain varies from an hour or less to many hours or even days.

Of aggravating or precipitating factors I would particularly mention cold and fatigue, each of which were specifically recorded in 14 instances; jolting, such as results from games or digging, horse-riding or motoring over rough roads, and even walking; mental stress or worry; purgatives; tobacco; and, in women, the menstrual cycle. The more irritable cases of mucous colic are very susceptible to fruit. Patients are sometimes more, sometimes less, comfortable when their bowels are confined, but aggravation of pain immediately after the act of defecation is common. Warmth, rest, hot baths, and open-air holidays with freedom from cares are among the relieving factors. Food sometimes gives temporary relief.

PHYSICAL FINDINGS.

To these disturbed sensations certain objective information can be added in a high proportion of cases, more especially if the opportunities for examination are frequent. The physical sign of the disease is an unusual palpability of some part or parts of the colon; this depends upon tonic rigidity, shortening and straightening of the affected loop. The colon can often be felt in the left iliac fossa in healthy persons or in patients without colonic disease, and simple palpability in this region cannot be regarded as pathological. In spastic colon it is felt as an unduly hard cord of small calibre. It is doubtful if the colon is ever palpable in its proximal or transverse portions in perfect health. In the condition of spastic colon, however, either of these portions may be felt as a firm rod or sausage-like tumour. This is sometimes, but by no means always, tender. The degree of palpability varies from time to time. The degree of palpability varies from time to time, and even in the course of a single examination, and is more likely to be remarked when symptoms are present. In those cases in which undue palpability was noted in my series the first part was affected in 18 instances; the second part in 8, the third part in 9. The first and third parts were simultaneously felt in 3, and all three parts in 4 cases. What Stacey Wilson aptly likens to a "cartilaginous ring" may sometimes be felt on inserting the finger into the rectum. Occasionally attacks of ballooning of the caecum are observed behind a spastic ascending colon.

The stools as a rule show nothing very characteristic excepting in the group to be separately considered under the heading of mucous colic. In the larger group there is no mucus excess or occasional very slight excess; no blood; and the colour varies within normal limits. There may, however, be fragmentation, and, in the presence of anal spasm, narrowing of the faecal mass. If purgatives are being used the motions may, of course, be "loose," "messy," and unsatisfactory.

Sigmoidoscopy is often both difficult and painful on account of spastic narrowing of the rectal and sigmoid lumen which is further stimulated by passage of the instrument. Fluctuations in the degree of spasm can be witnessed simultaneously with variations in the pain complained of by the patient. The mucosa looks perfectly healthy.

Less is to be gleaned from *X ray examination* than might be supposed. In the first place, the spastic state is intermittent and may not coincide with the examination. In the second place, a barium enema, which is commonly used in preference to the barium meal in colonic cases, may by its gradual introduction and gentle distension overcome existing spasm, just as Howship was able to bring relief in painful spasm with a large gruel enema; in the third place, when views are taken after evacuation of the bulk of the meal or enema, it is necessary to distinguish the appearances of a normal but partly emptied segment from a segment with spastic narrowing of its lumen. Examination after a barium meal is more likely to give positive evidence. In extreme cases the affected length of bowel appears as a thin thread or streak of barium, sometimes with a sharp line of demarcation from the better filled portions (vide Figs. 1 and 2). Normal haustrations, deepened with lesser degrees of spasm, become obliterated when the spasm is very pronounced. In some cases the whole transverse or descending colon or a longer portion is involved; in others, but less frequently, the spasm is localised to an inch or two. The localised spasms cause a more intense pain. Two other departures from the normal are important and will be discussed later. These are shortening and straightening of the affected loop.

MUCOUS OR MUCO-MEMBRANOUS COLIC (Muco-membranous Colitis).

I see no valid reason for placing these cases in a separate category. The abdominal pains described, the aggravating and relieving factors, and the radiographic appearances are identical. The chief differences are as follows: (1) the sex incidence, the cases being almost all in women; (2) the passage in attacks (usually after a period of constipation, chilling, anxiety, or fatigue) of large quantities of coagulated mucus, sometimes in casts or shreds or enveloping small scybalous fragments; (3) the more evident neurotic associations; (4) an exaggerated colonic tenderness with flinching and hyperalgesia but less definite palpability of the bowel. The sigmoidoscopic findings are as described in simple spastic colon. The mucosa is smooth and, at the most, slightly redder than normal.

DIFFERENTIAL DIAGNOSIS.

Judging by my own difficulties and those experienced by colleagues who have referred cases to me, the following conditions are among those which are simulated or suggested by the "spastic colon": (1) appendicitis, acute and chronic, (2) duodenal ulcer, (3) diverticulitis, (4) colonic carcinoma, (5) renal colic, (6) intestinal obstruction, (7) ovarian or tubal disease, (8) neurasthenia and hypochondriasis, (9) faecal tumours. Finally (10) the cases with mucus excess seem not infrequently to conjure doubts about the possibility of ulcerative colitis, or have been vaguely classified as "colitis."

(1) *Appendicitis*.—In one of my cases the hard lump in the right iliac fossa formed by the contracted colon during an attack of pain had led a surgeon to a provisional diagnosis of appendicular abscess. More

usually the persistence of symptoms leads to appendicectomy for a so-called "grumbling appendix." In simple spastic colon there is, as a rule, no pyrexia, guarding, vomiting, or cutaneous hyperalgesia. In acute exacerbations of mucous colic there may, however, be slight pyrexia, flinching (rather than guarding), superficial soreness, deep tenderness, and even sickness; but the previous history, the patient's psychology, and inspection of the stools generally establish the diagnosis. In simple spastic colon the interrogation, particularly in regard to the nature, duration, and localisation of the pain, and careful palpation along the course of the colon are usually adequate. (2) *Duodenal ulcer* may be simulated, firstly, because of associated pyloric or gastric spasm with food relief; and, secondly, because the colonic pain itself, although differently situated, may develop late after meals and be relieved by food. If there is any suspicion of duodenal ulcer as an alternative or additional diagnosis a full investigation should be advised. (3) *Diverticulitis*. In the left-sided cases particularly this possibility must be borne in mind, but the type of individual affected is usually different, the victim of diverticulitis being commonly well nourished and less commonly neuropathic. The inflammatory tenderness and thickening of pericolicitis and pyrexia during exacerbations are distinctive. *X ray examination* after a barium enema should be made in case of doubt. (4) *Colonic carcinoma* has frequently been feared in cases of spastic colon because the patient himself or his physician has discovered a hard lump in the course of the colon. The smoothness of the tumour, its sausage or rod-like formation, its mobility in the case of the ascending or transverse colon, its variations in size and hardness, or complete disappearance under observation or in a hot bath are helpful points in differentiation. The absence of obstructive symptoms on the one hand, and of diarrhoea or passage of blood on the other, and generally a very long history of abdominal discomforts are reassuring features. If doubts persist the aid of the radiologist, sigmoidoscopy, and chemical and cytological examination of the stools should be invoked. (5) *Renal colic* is only likely to be simulated in the occasional cases with very severe pain (vide Case 3, in which the hardened colon was mistaken by myself and others for the left kidney). (6) *Intestinal obstruction* was feared in Case 4, in which the complication of caecal distension was present. (7) *Ovarian or tubal disease*. At one time it was not uncommon for operations on one or both ovaries, but especially the left, to be performed for spastic colon. The fallacy probably arose from the aggravation of colonic pain which sometimes accompanies the period and from the association with dysmenorrhoea. (8) *Neurasthenia and hypochondriasis* may appear appropriate labels in some cases of spastic colon, but they do not embody an adequate explanation of the pain and physical findings. (9) *Faecal accumulations* can be disposed of with enemata. (10) "*Colitis*" is an inaccurate pathology. I have had several cases of mucous colic referred to me with a diagnosis of *ulcerative colitis*, but the two conditions bear little resemblance to one another. In the more serious disease an ill and frequently anæmic and wasted patient gives a history of watery diarrhoea and passing blood and mucus, commonly with a febrile, dysenteric onset. The diagnosis is completed with the sigmoidoscope.

FREQUENCY OF SPASTIC COLON.

Taking all grades of the condition, allowing for its varied appellations and deceptions, and judging by information received from colleagues in general practice, I can only conclude that spastic colon is a common disorder. On the basis of consulting and hospital experience I should say that it ranks high among the causes of chronic abdominal distress. Numerically in my index it is more frequent than gastric ulcer, but less frequent than duodenal ulcer, conditions which are far more likely to be referred for a second opinion.

NATURE OF THE DISORDER.

"Spastic colon" falls into the category of the visceral neuroses. Its association with certain physical and psychological types; its intermittent behaviour; its aggravation by circumstances which depress or harass the higher centres; and the absence of all evidence of an associated organic lesion, give credence to this view. It is a close ally to bronchial asthma, in which an inherited irritability of the bronchial centres and a sensitiveness to certain local, psychic, and peripheral stimuli are, on Hurst's⁹ showing, so apparent. Just as with asthma so with spastic colon cases occur in which spasm alone is the outstanding feature, and others in which mucorrhœa is superadded. Asthma is sometimes coincident with colonic spasm in the same patient or recorded in a near relative. The stimuli which may provoke and perpetuate an attack of colonic spasm include (1) local stimuli (purgatives, constipation), (2) central nervous stimuli (worry), (3) external peripheral stimuli (cold). The same irritability of plain muscle is often simultaneously manifest as bladder frequency and even bladder pain, especially in female sufferers from spastic colon; in pyloric spasm; spasmodic dysmenorrhœa; and in the vascular spasm which gives rise to "dead fingers."

NATURE OF THE SPASM AND PAIN.

In obstructive or irritative lesions of the colon there is increased peristaltic activity with more or less rhythmical gripping due to the passage of waves of contraction involving successive groups of circular fibres. In spastic colon no such rhythmical movements are provoked, but the tonus or posture of the muscle-fibres, including the longitudinal fibres, is modified in such a way as to impart a sustained shortening, with rigidity and narrowing of the lumen, to portions of the bowel wall often many

inches in extent. The hardness and equally the straightening and shortening of the affected loop cannot be otherwise explained. I was at one time puzzled by finding a hardened and horizontal transverse colon crossing the epigastrium, for although this is its anatomical situation I knew that the radiologist more frequently showed this structure

Tonic spasm of transverse colon with ballooning of cæcum (erect).

as a festoon in the middle or lower abdominal planes and sometimes even in the true pelvis. Examination of Figs. 1 and 2, copied from radiograms in my possession, will show what remarkable straightening may occur and at once explains the clinical observation. Surgeons sometimes witness the phenomenon of tonic hardening in the course of a laparotomy when the affected loop becomes rigid, pale, and erect in the wound. I know no clinical condition which better supports the hypothesis that visceral pain originates in the viscus and is due to increased tension in the muscle-fibre than spastic colon. With no inflammatory disease to involve the other coats of the bowel or neighbouring tissues, and so to confuse the issue, it is possible to demonstrate in these cases at once a complete absence of somatic hyperalgesia and well-defined pain and tenderness in the affected bowel itself, a pain and tenderness which increase

when the hardening increases and diminish when it diminishes. The sustained and aching character of the pain accords well with this durable modification of tonus or posture, and contrasts with the sharper, transient agony of peristaltic colic.

ILLUSTRATIVE CASES.

CASE 2.—*Illustrating the influence of cold, the simulation of appendicitis, and the cause of the pain.*—A young and athletic lady, aged 25, developed pain in the right iliac fossa on a long voyage.

on a long voyage. The ship's doctor diagnosed appendicitis, but would not operate on board. On arrival in England her own medical adviser and a surgeon saw her and concurred in the diagnosis, but freely admitted that the appendix when removed was "disappointing." The other organs were healthy. The pains recurred and she was brought to see me. I obtained an earlier history of many attacks of sudden and intensely severe pain coming on ten minutes after a long swim, in which she

Tonic spasm of descending colon (same case as Fig. 1) twenty hours later (supine).

CASE 3.—*Illustrating difficulties in differential diagnosis, the occasional severity of the pain, and aggravation by an enema, jolting, &c.*—An infant officer, aged 41, consulted me on Feb. 25th, 1926, for severe pain in the left subcostal region passing through to the back at the same level. He had also felt the pain in mid-epigastrium where he had been tender. He had suffered similar symptoms a year and also five months previously, but less severely. The pain was liable to come one or two hours after food, and was sometimes relieved by eating. Jolting definitely aggravated it. His actual sensations he likened to "a lump of dough stuck and swelling as though about to burst." He was lean, tense, and tremulous, and very tender in mid-epigastrium. I made a provisional diagnosis of gastric ulcer and put him into a nursing home for observation. On Feb. 27th he had a very severe attack of pain below the left rib margin and radiating down towards the groin. *The pain immediately followed an enema.* Morphine was given on more than one occasion. He was tender under the left ribs and I queried feeling the kidney. Jarring the loin also caused pain. Urine normal. His wife then remembered that for years he had had an occasional day in bed for left-sided pain. While I was away for a week-end, the patient, my deputy, and the nurses all noted the presence of a lump below the ribs which was gone on my return. I now decided to regard the symptoms as renal. A surgical colleague who saw him with me concurred, but cystoscopy and pyelography were negative. The pain continued, and he was explored on March 14th, all investigations having proved negative and all medical treatment unavailing. A slightly fibrotic appendix was removed, and adhesions between the duodenum and gall-bladder were freed. No ulcer, gall-stones, growth or other abnormality were demonstrable. He was not relieved of his symptoms by the operation, although reassured in his mind by the findings. I was then able to satisfy myself that both the pain and the lump were colonic and due to tonic contraction. I have seen only a few other cases in which the pain was so severe and none so deceptive in symptomatic associations. I saw this patient, who remains on duty, recently, and was able to feel the hardened colon to the left of the navel. He is quite clear that jolting and cold, which I had come in the

interval to recognise in other cases as important aggravating factors, are very definitely so in his case. I should clearly have paid more attention in his first bad attack to the influence of the enema.

CASE 4.—*Illustrating the occasional severity of symptoms, ballooning of the cæcum, the shortening and straightening of the colon, and the accuracy of localisation by the patient's gesture.*—I was consulted in May of the present year by a woman aged 40. From girlhood she had suffered from constipation and a liability to nausea, and had been prevented by her poor health from taking up work in which she was interested. In 1921 she had acute gangrenous appendicitis. Since then she had, in the words of her medical adviser, had three or four attacks "almost like a partial obstruction." These start with feelings of pain and weight in the cæcal region where a big bulge appears. In her last attack she could "feel the bowel like a lump," and was in pain for four or five hours continuously. The pain also passed straight across her abdomen to the left. Lesser attacks were brought on by work in the garden, and could be cut short by lying down. There was aggravation by purgatives and her pain was worse after defecation. On palpation I was able to feel a hardened colon which again "faded" under my hand. The radiograms showed an extreme degree of colonic spasm affecting first the transverse and later the descending portion. During the examination she surprised the radiologist by accurately tracing the course of the transverse colon by her sensations. This straight course from hepatic to splenic flexure is well shown in Fig. 1.

TREATMENT.

Most patients with "spastic colon" have been walking in fear of organic disease; many of them have been told that they have organic disease; cancer-phobia is frequently present; operations may have been advised or already performed. The first duty of the physician is therefore full reassurance. With this must be combined a simple explanation as to the nature of the disorder and the mode of origin of the pain. Under general hygienic measures the importance of mental and physical relaxation, of holidays, of moderate exercise, of warmth, and a sensible mixed diet must be enumerated. Often the diet has been cut too low and fruit and vegetables have been too rigorously excluded. The bulky starchy foods, potatoes, beans, and peas, which predispose to intestinal flatulence, are better avoided, but fruits of all kinds, excepting those with tough skins and seeds, and the softer green vegetables should be liberally prescribed together with wholemeal bread and farm produce as a natural treatment of the costive tendency. Tobacco may require restriction or even be forbidden for a long test-period. Purgatives must be entirely forbidden, but lubricants may be given. Belladonna or hyoscyamus in full pharmacopœical doses helps to relax the spasm. Bromides should be reserved for the anxious and "jumpy" patients, and withheld in the case of the more jaded and depressed. There is commonly restlessness with a furrowed brow, and hypertonus of skeletal muscles. Psychotherapy plays an important part in the treatment of such cases. Jackson¹⁰ has described a method of treatment by "progressive relaxation" in which clinical improvement is shown to coincide with a return to normal in the colonic radiograms and a diminution in the briskness of the knee-jerks. The good sleep enjoyed by most patients, even when suffering bad pain by day, is probably due to the relief afforded by natural muscular repose. In some cases the sallow complexion and lassitude and a furred tongue during the attacks seem to suggest an element of what—for want of a more precise term—we must continue to refer to as intestinal toxæmia. I think it must be in these cases especially that Stacey Wilson obtains his successes by exhibiting liquor hydrarg. perchlor. with liquor ferri perchlor. I have not tried his prescription extensively, but in one case it seemed to bring about a remarkable improvement when other remedies had failed and the patient was begging for an exploration. In cases with severe pain and in exacerbations of mucous colic, initial large warm enemata administered very slowly, both to give lavage and to overcome the spasm, and rectal injections of warm liquid paraffin (4 or 5 oz.) to be retained overnight, are useful. The disorder, being like asthma and migraine, so largely

dependent on constitutional factors, is difficult to "cure," but repeated reassurances and rational treatment will often mitigate symptoms even in bad cases. In milder cases there may be complete relief.

CONCLUSION.

I have attempted a somewhat detailed analysis of the clinical picture of spastic colon because the diagnosis of the condition should generally be possible on clinical grounds. Furthermore in functional disorders of this kind special investigations inevitably give a high percentage of negative results. The recognition of spastic colon as an occasional cause of very severe abdominal pain and as a common cause of persisting or recurring pain in the right iliac fossa is, I believe, especially worthy of emphasis. Writing of these visceral neuroses in 1906 Hawkins said, "They are at this moment particularly worthy of study, owing to the advance of abdominal surgery, not because they are amenable to surgical treatment, but rather because they need protection." I think it should be accepted that they still need protection, and that for this and other reasons they are still worthy of study.

THE RELATION OF ARTHRITIS OF THE SACRO-ILIAC JOINT TO SCIATICA,

WITH AN ANALYSIS OF 100 CASES.*

By W. YEOMAN, M.B. LOND.,

HONORARY PHYSICIAN, ROYAL BATH HOSPITAL, HARROGATE.

The part which the sacro-iliac joint plays in "lumbago" and "sciatica" has long been a source of speculation, and in America "sacro-iliac strain" or subluxation is a common diagnosis. My attention has been drawn to the apparent frequency of a spur or irregularity of bone at the lower end of the sacro-iliac joint, and the analysis of a number of cases may be of some value. The series consists of 100 cases admitted to the Royal Bath Hospital, Harrogate, with a diagnosis of sciatica, in all of which radiograms of the sacro-iliac and lumbo-sacral joints had been taken. In all radiograms the hip was included, and in most some or all of the lumbar vertebrae were shown.

Anatomy of the Joint.

In order to obtain a clear conception of the rôle which the sacro-iliac joint plays in the causation of sciatica it will be necessary to summarise briefly the anatomy of the joint and its relationship with the lumbo-sacral cord.

In addition to descriptions in standard text-books of anatomy, reports on a series of dissections of the joint have been made by Albee¹ and Brooke.² In 50 specimens Albee found a perfect joint with synovial membrane, cartilage, joint cavity, and well-formed capsule. The joints before being opened were injected with methylene-blue, which showed that the synovial membrane distended and retracted along the anterior inferior aspect of the joint during movement. The lumbo-sacral cord was found in close proximity to the lower third of the joint. Brooke based his findings on 200 dissections, and confirmed Albee's work. He found that many males in late middle and advanced

* Abstract of paper read before the Harrogate Medical Society.

life had ankylosed joints, and considered these to be senile pathological changes; no females showed ankylosis. He summarises by saying that the joint is diarthrodial in type and probably takes part in movements backwards and forwards of the lumbar spine.

Danforth and Wilson³ made exhaustive dissections of the lumbo-sacral cord, and found that the foramen between the fifth lumbar vertebrae and the sacrum was the smallest intervertebral foramen, yet the fifth lumbar nerve was the largest nerve. This significant fact seems to justify their conclusion that the lumbo-sacral cord is less likely to receive damage from the sacro-iliac joint because there is no canal, and therefore the chances of nerve injury are much greater in the lumbo-sacral region. The fifth lumbar nerve, however, lies in close proximity to the sacro-iliac joint and the first and second sacral nerves join it to form the lumbo-sacral cord at the lower margin of the joint, but are separated from it by the pyriformis muscle and its fascia of origin. Insufficient attention has been paid to the rôle of the pyriformis in the causation of sciatica; the muscle arises from the pedicles of the second, third, and fourth sacral vertebrae and adjacent part of the bone lateral to the sacral foramina. It is therefore in contact with the anterior ligament of the sacro-iliac joint and the roots of the first, second, and third sacral nerves, and its lower border is closely related to the whole trunk of the sciatic nerve. The pyriformis is an abductor and external rotator of the hip, and is a flexor of the hip in the act of walking.

It will be advantageous to consider briefly the segmental sensory distribution of the leg. The fourth lumbar nerve supplies the inner side of the leg from just below the knee to the ankle and inner side of the foot, the fifth lumbar the outer side of the leg and dorsum of the foot, the first sacral the sole of the foot, dorsum of the toes, outer side of foot, and some way up the back of the leg; the second sacral supplies a long strip stretching down the middle of the back of the thigh from the fold of the buttock to below the popliteal space. In addition, the gluteal muscles are supplied from the first and second sacral. Broadly speaking, pain is referred to the posterior aspect of the thigh as well as to any part of the lower leg, and to the inner aspect of the thigh in certain cases.

Résumé of Literature.

The literature on low back pain and sciatica reveals a difference of opinion as to the part taken by the sacro-iliac joint.

As reported in THE LANCET,⁴ Lusskin and Sonnen-schein⁵ offer an explanation of how sacro-iliac sprain is brought about, and describe how the resulting symptoms of low back pain and pain shooting down the leg are relieved by strapping in acute cases and by an appropriate brace. On the other hand, Albee¹ who, 20 years ago, held similar views, now⁶ considers these symptoms are due to "myofascitis," his own word to describe inflammation of muscles and fascia, apparently covered by the older word "fibrositis." He states that over 90 per cent. of cases of "lumbago," "sacro-iliac," "sciatica," &c., are examples of myofascitis, that the insertions of fascia and muscles into the bony structure of the sacro-iliac joint are tender, and that 90 per cent. of these patients have symptoms referable to the colon.

The literature of disease of the joint is not so profuse as that of joint strain, but Barré and Dupré⁷ recognise "sacro-iliac sciatica," although they consider that sacro-iliac arthritis is usually tuberculous; they differentiate this syndrome from primary sciatica by the fact that in the former the buttock wastes before the leg and foot, and pressure on the nerve is painful. Gowers stated that when the disease is within the pelvis tenderness of the trunk of the nerve is slight in proportion to the pain. Against this evidence implicating the sacro-iliac joint is the opinion of almost as many observers who blame abnormalities of the lower lumbar vertebrae and lumbo-sacral joint for this type of sciatica. Putti⁸ considers that the hypothesis lacks anatomical and clinical support. I hope to advance some clinical evidence to show that

in certain cases there is a connexion between arthritis of the joint and sciatica.

Putti calls attention to anomalies in the plane of the articulations between the lumbar vertebrae and between the fifth lumbar and sacrum. To obtain radiological evidence in support of this necessitates numerous radiograms, and a stereoscopic view is almost essential. I have not felt justified in having this done, so that I have only two clear pictures of this anomaly.

The many views on the causation of sciatica have one item in common, a recognition of a lesion in the lumbar and sacral region, indicating a tendency to regard sciatica as a symptom and not a clinical entity, with attention focused on the roots of the nerve rather than on the trunk.

Clinical records are few, but Danforth and Wilson,³ Doub⁹ and Rogers¹⁰ all report series of cases. Rogers¹⁰ in 50 cases found lesions of the lower spine in 49, the remaining case being carcinoma of the prostate. He classifies 17 cases as acute strain of the lower spine, most of them representing an acute lesion of the sacro-iliac joints, 21 as chronic strain of the lower spine, 8 as hypertrophic arthritis of the lower lumbar spine confirmed by radiograms, and 4 as tuberculosis. Cone¹¹ has reported two cases which showed a "haziness" in the sacro-iliac area. They had received much treatment for a relaxed sacro-iliac joint, but were only relieved when a spicule of bone was removed from the great sciatic notch and the nerve freed from adhesions. Discussing the diagnosis of arthritis of the sacro-iliac joint on the evidence of bony overgrowth at its lower margin, Verrall¹² remarks that "inexperienced radiologists often report the presence of arthritis of this joint when none is present, basing their diagnosis on lipping of the joint margin at the lower end. This apparent lipping is due to a groove, in which a small vessel runs, which is bridged by a ligament described by Derry of Cairo and used by him as a sex indication in investigating the remains from certain pre-dynastic cemeteries in Nubia, the groove being better marked in the female, especially after many pregnancies or if congenital relaxation is present. However, skiagrams do show arthritis which is generally of the atrophic variety." The radiograms in my series have been re-examined by Dr. C. G. Hitchcock, and include two examples of the groove which Verrall describes. The report of one case is as follows (Fig. 1):—

Female, age 20, unmarried, stillroom maid. Pneumonia two months before admission. Pain in back started 14 days before the pneumonia. Catamenia regular but associated with constipation and painful defecation. Tenderness over the sacrum down to the coccyx. Rectal examination showed acute tenderness over inside of pelvis, especially at lower margins of the sacro-iliac joints. X ray showed tilting of the lumbar spine to the left, due to old trauma or disease and well-developed bony spurs at the lower borders of the sacro-iliac joints.

One other picture showed a similar condition in a miner, aged 50, who had also marked spondylitis of the lumbar vertebrae.

Analysis of 100 Cases.

	Average age.	Youngest.	Oldest.
Men 77	44	18	72
Women 23	44	18	72

Occupation.—The women were in no particular trades, the majority being married and in charge of homes. The occupations of the men were various; 25 were miners, and 72 per cent. were employed in occupations requiring much back movement—e.g., labourers, gardeners, engineers, &c. This suggests sustained back-effort as a predisposing cause.

Classification of Lesions (100).

1. Arthritis of sacro-iliac joint alone	19	} 36
2. Ditto, and other lesions	17	
3. Abnormality in region of sacro-iliac joint	8	} 12
4. Arthritis of hip alone	4	
5. Ditto, and lesion of lumbar vertebrae	20	} 21
6. Various lesions of lumbar vertebrae	21	
7. Normal appearance	21	

These figures require amplification. Arthritis of the sacro-iliac joint was diagnosed if the joint showed

a blurred outline or fusion of the articular surfaces or if there was erosion or osteophytic outgrowth at the lower border of the joint. (Fig. 2). In Group 2 the "other lesion" was spondylitis of the fourth and fifth lumbar vertebrae and, in one case, sacralisation of the fifth lumbar vertebrae; in four cases the hip showed evidence of arthritis. Group 3 was made up as follows: malignant disease of the prostate with secondary deposits in the ilium; a cystic tumour of the ischium; two cases of calcified glands in close relationship to the lower end of the joint; two cases of the marked artery-notch mentioned previously; one case where the sacrum was deep to the iliac crests; and one case showing a displacement of the left lateral mass of the sacrum, perhaps an example of the "sacro-iliac strain" of the American writers.

FIG. 1.

Tracing of radiogram showing well-marked grooves, as described by Verrall, on both sides.

The remaining groups have little bearing on the points raised in this paper, but only two cases showed abnormalities of the articular facets of the fifth lumbar and sacrum as described by Putti.

Ankylosis of the sacro-iliac joint was present in nine cases, all men, but the age-incidence was younger than in the cases described by Brooke; only four of mine were over 50, and the youngest was 22.

Arthritis of a joint which can be demonstrated by a radiogram is by no means in an early stage, so that the above findings are significant. Where a radiogram shows alteration there must be a large amount of inflammatory reaction in the adjacent soft tissues, a condition of periartthritis. It is justifiable to suppose that such a state of things occurs in the sacro-iliac joint. Where joint movement is so slight the condition is unlikely to cause symptoms until it is advanced, and may not be noticed until some extra strain or unusually sudden movement is made involving the muscles in the neighbourhood of the joint. Any lesion of the sacro-iliac joint may cause inflammatory reaction of the pyriformis muscle and its fascia. This fibrositis will involve the first and second sacral roots if not the whole trunk of the sciatic nerve, and there is evidence of this as shown by loss of tone and wasting of the glutei with increased hyperaesthesia over the gluteal area. Loss of tone in the glutei may be present without wasting of the thigh or leg, and where there is no lesion of the sacro-iliac joint there may be wasting of the thigh or leg and no loss of tone in the glutei. The first and second sacral are the segments responsible for the glutei, and are the roots most liable to damage by a lesion of the sacro-iliac joints. The condition of the glutei resembles an irritative lesion rather than wastage from disuse, whereas the wasting in thigh and leg when present is from disuse. Frequently when the glutei show gross loss of tone and wastage there is no pain on deep palpation of the sciatic nerve in the thigh.

Clinical Examination and Diagnosis.

The history varied widely, but in the majority pain started in the lower back and gradually spread down the back of the leg. Many had had previous attacks; the onset was usually gradual, only 15 being acute. In 15 cases the pain commenced in the hip, but there was no abnormality in the hip movement or in the radiogram of the joint. As the hip derives its nerve-supply from the sacral plexus, among other sources, this points to irritation of the sacral roots.

There is always loss of tone in the glutei if a lesion of the sacro-iliac joint can be demonstrated by X ray. Loss or diminution of the Achilles tendon reflex was not a marked feature, being noted in two cases only. One of these showed sacralisation of the left lateral mass of the fifth lumbar, and the other showed alteration in the fourth and fifth lumbar vertebrae with arthritis in one sacro-iliac joint. As the segment regulating this reflex is the first sacral, one would have expected it to be more frequently affected.

Much has been written about postural abnormalities in sacro-iliac strain and stress has been laid on the type of scoliosis. Scoliosis was not a feature in the cases under review, and when present was due either to gross change in the lumbar vertebrae or to muscle-spasm, disappearing when the involved muscles were relaxed. Frequently there is obliteration of the normal lumbar lordosis and a flattening out of the lumbar spines; in acute cases this is marked, especially with the patient prone. In an acute lesion of the sacro-iliac joint there is inability to rest the abdomen on the couch, the body being supported on the chest and knees with the back and thigh held rigid by muscular spasm. If pressure is put on the pelvis to force it down to the couch there is acute pain in the affected joint, due to stretching of the anterior ligament of the sacro-iliac joint. The course I have adopted for demonstrating a lesion of the sacro-iliac joint is as follows:—

The patient being prone on the couch the knee is flexed and a firm grip taken of the ankle while the other hand is placed over the sacro-iliac joint; the hip is then passively hyperextended by lifting the knee off the couch while the pelvis is kept on the couch with the other hand. This procedure stretches the anterior sacro-iliac ligament and elicits pain in the presence of a lesion in the joint. In a normal person this action is painless. This manipulation has been frequently mentioned in literature and is worth more attention.

X rays have confirmed my diagnosis in an appreciable number of cases where manipulation suggested

FIG. 2.

Well-marked osteo-arthritis of left sacro-iliac joint. (Tracing of radiogram.)

the presence of a lesion, and in no case has a radiogram shown a lesion of the sacro-iliac joint when pain was not elicited by the manipulation.

It has been assumed that Kernig's or Lasègue's sign stretches the sciatic nerve; American writers consider that limitation in this movement is due to spasm of the hamstrings, pointing out that owing to their origin from the ischial tuberosity any spasm of these muscles exerts a pull on the pelvis and causes movement of the sacro-iliac joint.

But if the hip is flexed and the knee extended, the fingers, deep in the popliteal space, feel the internal popliteal nerve tighten when the foot is dorsiflexed, showing that it is possible to exert tension on the nerve. The thigh must make an angle of 150° at least with the trunk before the hamstrings are put on the stretch. In the present series of cases it was possible to flex completely and painlessly the extended leg on the trunk in seven cases, whereas the procedure of hyper-extending the thigh produced pain in the sacro-iliac joint, and a lesion was subsequently shown by the radiogram.

Another recognised method of eliciting pain in the sacro-iliac joint is compression of the iliac crests; Verrall¹² considers that pain felt over the joint on

compression of the iliac crests or of the os pubis is conclusive evidence of a sacro-iliac lesion, and that its absence contraindicates such a diagnosis. I have not been able to demonstrate the value of this sign in any case in this series. The only cases in which I have elicited the sign have been either fractures of the pelvis or some gross destructive lesion—e.g., tuberculosis involving the sacro-iliac joint. Forcible separation of the iliac crests would be more likely to cause pain if the sacro-iliac joint was affected, by stretching the anterior sacro-iliac ligaments.

Other devices for demonstrating inflammation of the joint have been described; I have not used them systematically but have relied for a diagnosis on the wasting and loss of bone in the glutei, Kernig's sign, and hyperextension of the hip. It is necessary to emphasise the importance of a rectal, supplemented where possible by a vaginal examination, in all cases of sciatica. By this procedure it is possible to palpate the sciatic nerves and the lower margins of the sacro-iliac joints, and to eliminate carcinoma of the prostate or any gross intrapelvic lesion.

Treatment.

Treatment is important from the economic point of view. Sciatica affects the wage-earning community at an age when their productive capacity should be at its height and incapacitates for considerable periods. If this paper, which only considers one possible cause, concentrates attention on the nerve roots rather than on the trunk, it will have served its purpose.

It is significant of the change in treatment during the last few years that, as far as I know, no case of sciatica in the hospital during the last six years has had an injection into the nerve sheath, nor had the nerve forcibly stretched under an anæsthetic. Twenty years ago these procedures were common. If my conception of the cause of some sciaticas is correct, the rational line of treatment is to assume that the sacro-iliac joint is the seat of a so-called rheumatic infection. Having eliminated gross disease in the pelvis and a tuberculous infection, it is necessary to exclude any possible source of infection—as in arthritis in any other joint.

The main treatment at the Royal Bath Hospital is hydrotherapy, and I have found the sulphur bath with subaqueous douche most valuable. This may be followed by the Scotch douche or a massage douche bath when the acute pain has subsided, but massage given in the acute or subacute stage aggravates the condition. In conjunction with this, sulphur water by the mouth ensures a complete daily evacuation of the bowels, and in suitable cases colon lavage with sulphur water is employed. A course of treatment of this kind usually extends over three or four weeks, and in the majority of cases results in great amelioration, if not complete disappearance of all symptoms.

For the acute case I have found nothing so beneficial as intravenous non-specific protein. I use T.A.B. vaccine and the same technique as I have described in a previous communication.¹³ The results have been even more encouraging than in generalised infective arthritis. I will quote two cases from this series, one with and one without a lesion of the sacro-iliac joint.

CASE A.—Male, aged 39, chauffeur. Influenza five months before admission followed by pain down the right leg. Six weeks in bed. All teeth removed recently. $\frac{1}{2}$ inch wasting right thigh, buttock folds equal, reflexes normal, great pain on stretching right sciatic nerve. No pain on movement of sacro-iliac joint. Scoliosis with concavity away from the lesions; can only walk with great pain, and with the help of two sticks.

X Ray Report.—Sacro-iliac joints normal. Irregularity between fourth and fifth lumbar vertebra, convex towards right side; thickening in right lateral articulation between fifth lumbar and sacrum.

Treatment.—Hydrotherapy, as indicated above, for 19 days with little improvement; as it was urgent that he should return to work injections of T.A.B. vaccine were given intravenously. After the first injection the pain was much easier, and after the fourth he was able to stand massage and had discarded his sticks. He was discharged 20 days

after the commencement of the injections with no pain on stretching the sciatic nerve, and his only complaint was of a dull ache in the leg after a long walk.

CASE B.—Male, aged 22, mechanic. Rheumatism started in shoulder two years prior to admission, and gradually spread to knees and right hip. Pain and limitation of movement in right shoulder, right knee, right hip; pain in right sacro-iliac joint; wasting of the thigh muscles and loss of right gluteal fold. Walks with help of two sticks, and in great pain.

X Ray Report.—Chronic inflammatory changes in the sacro-iliac joint. Hip joint normal.

Treatment.—Five injections of T.A.B. at four-day intervals with 40 minutes' general massage daily, except on the days of injection. Twenty-one days after the first injection he walked without sticks, the movements at the shoulder and hip were unrestricted, and the knee was greatly improved. There was practically no pain in the sacro-iliac joint.

Conclusions.

The above series of 100 cases represents less than one-fifth of the cases of sciatica admitted to the hospital during the past six years, and was selected because radiograms of the sacro-iliac joint had been taken. The following conclusions seem justifiable:—

1. Arthritis of the sacro-iliac joint accounts for an appreciable proportion of cases of sciatica, 36 per cent. in this series.
2. The symptoms are due to a peri-arthritis involving the anterior sacro-iliac ligament, the pyriformis muscle, and the adjacent radicals of the sciatic nerve, chiefly the first and second sacral nerves.
3. It is possible to diagnose this condition with a reasonable degree of certainty.
4. X rays confirm the diagnosis in many cases by showing spur formation, indistinct outline, or fusion of the sacro-iliac joint.
5. Treatment should follow the course indicated in arthritis or peri-arthritis of other joints of the body.
6. For the acute condition, intravenous injections of T.A.B. vaccine give the best chance of removal of symptoms in the shortest possible time.
7. Strain of the sacro-iliac joint may be a predisposing factor in the condition, but is not a common sole cause of sciatica in this country.

In conclusion, I should like to express my sincere thanks to my colleagues on the staff of the hospital for allowing me to supplement my cases from theirs. My thanks are also due to Dr. Hitchcock, one of the honorary radiologists, who kindly scrutinised the radiograms, and to Mr. Lissimore for his pen-and-ink sketches and the slides he made to illustrate points raised in the paper.

INCREASING DEMAND FOR RADIUM TREATMENT.—The urgent need of an adequate supply of radium for the treatment of cancer patients for West Lancashire has long been felt in Liverpool and a scheme is to be brought forward to establish a radium institute in Liverpool at a cost of £100,000. A representative committee of the Cancer Hospital and the four large general hospitals and other institutions is considering the question. Under the scheme patients would not need to be sent to Manchester, as at present, for radium treatment.—The Leeds General Infirmary has issued an appeal for £25,000 with which to buy a supply of radium for the treatment of cancer. It is stated that there is at present no radium in the infirmary.

TREATMENT AND PROPHYLAXIS OF SCARLET FEVER WITH SPECIFIC ANTITOXIC SERUM.*

BY JAMES C. B. CRAIG, M.D., D.P.H. EDIN.,
SENIOR MEDICAL ASSISTANT, EDINBURGH CITY FEVER HOSPITAL.

THE ætiological relationship between scarlet fever and certain specific strains of the hæmolytic streptococcus has been established through the work of Tunnickliff, Gordon, Dochez, Dick and Dick, Zingher, and others, and their work has changed the views of investigators on the treatment and control of this disease. The injection into horses of these specific strains and their toxic products has been shown to produce an antitoxic serum, for which various workers have claimed favourable therapeutic results. Park,¹ of New York, in his observations upon the use of an antitoxic serum in the treatment of scarlet fever, emphasises the necessity of giving a sufficient dose at the earliest possible moment. He agrees with previous investigators that antitoxin has little effect on septic complications already developed, but that before their onset the serum appears to be of service in preventing them. Gardner Robb,² Harries,³ and Benson and MacIver⁴ report satisfactory results from the use of serum in the prompt neutralisation of the specific toxæmia of the disease, and a beneficial effect in lessening the incidence of subsequent complications. Cushing⁵ reviews the antitoxin treatment of 500 cases of scarlet fever at the Alexandra Fever Hospital, Montreal. He found that the action of various preparations of serum differed only in degree, the effects varying according to strength and concentration. Antitoxic serum was given to every definite case of scarlet fever, and the findings were controlled by studying the hospital statistics for the previous year of cases of the same clinical type.

Method Adopted.

During the period October, 1926-27, I had the opportunity of treating with antitoxic serum, in the City Fever Hospital, Edinburgh, 500 cases of simple scarlet fever, 10 cases of septic scarlet fever, and 2 cases of the toxic type of the disease. The practice followed was to administer serum, on the day of admission to hospital, to every definite case of scarlet fever of the simple type within the first three days of disease. Included in the series are a few cases to whom serum was given on the fourth day of disease. These cases were of more than average severity, and it was thought advisable to give them the benefit of serum therapy, although it is generally admitted that by this time patients have passed the stage at which antitoxin treatment proves beneficial. Cases of a very mild type or of doubtful diagnosis were not included.

It was not possible to secure adequate control cases admitted during the same months, as I wanted to study the results of serum therapy on as large a number of cases as possible within the prescribed period. For controls, therefore, I studied the clinical course of a similar number of cases of definite scarlet fever admitted to hospital during the preceding year, October, 1925-26. The cases selected from the hospital records were of the same age-period and the same clinical type, and had been admitted to hospital on the same day of disease and on a corresponding date to those in the serum-treated series. Though it is recognised that scarlet fever varies considerably in its severity from year to year, the control cases were selected so as to be comparable in every detail with those treated by serum. This method of comparing and contrasting results in serum and non-serum treated cases is a reliable one, provided the number of cases is large.

* The contents of this paper form a résumé of the work embodied in a thesis which was accepted for the degree of M.D. of the University of Edinburgh.

Type of Serum and Methods of Standardisation.

The preparation used was a concentrated scarlet fever streptococcus antitoxin supplied by (1) Messrs. Parke, Davis and Co. (P., D. and Co.); (2) Messrs. Burroughs Wellcome and Co. (B. W. and Co.). These sera, before they are put on the market, have their antitoxic titre tested, and 10 c.cm. or less of the P., D. and Co. preparation is said to contain an efficient therapeutic dose, able to neutralise 500,000 skin-test doses of scarlet fever toxin. The potency of the B. W. and Co. preparation is likewise tested, and the recommended therapeutic doses are: 10 c.cm. for mild cases, 20 c.cm. for severe cases, and 20-50 c.cm. for cases of a very severe type.

To corroborate these statements the potency of samples of the sera were tested by the Schultz-Charlton blanching test and the toxin-antitoxin neutralisation test. In the former method an intracutaneous injection of a fixed quantity of serum in varying dilutions was performed on patients exhibiting a typical scarlatiniform eruption of under 48 hours' duration. An attempt is thereby made to determine the smallest amount of serum which will show local blanching of the rash. The results obtained varied, but out of a total of 18 patients tested, definite blanching occurred in four cases with 0.2 c.cm. of 1 in 16,000 dilution, in rashes of under 24 hours' duration. In all cases blanching was obtained with 0.2 c.cm. of dilutions up to 1 in 4000 of the serum in question. The results were similar for both types of serum.

The rationale of the second method is to find the smallest amount of antitoxin which will neutralise one skin-test dose of a standard scarlet fever toxin in a strongly Dick-positive individual. From this quantity we can establish a unit of antitoxin (i.e. the amount which neutralises 100 skin-test doses of toxin), and can thus calculate how many units of antitoxin are contained in a given amount—e.g. 1 c.cm. of the antitoxin. Thirty-four Dick-positive diphtheria-convalescent children were tested, and from the results in 14 of these cases the serum was calculated to be able to neutralise 50,000 skin-test doses of toxin per c.cm. Again the findings were not consistent in all the patients tested and, taking the results as a whole, the potency of the samples of sera in terms of the ability to neutralise scarlet fever toxin seemed to vary between 10,000 and 50,000 skin-test doses per c.cm.

Prophylactic and Therapeutic Dosage of Serum.

There are many difficulties in the methods of standardisation of scarlet fever antitoxic serum, and the dosage of these preparations is therefore somewhat uncertain. The method employed in the prophylaxis of scarlet fever by antitoxin is the production of passive immunity, which is expressed in terms of the smallest amount of antitoxin which will render a Dick-positive reactors negative and keep them so for a period of time beyond the longest incubation period of the disease.

A batch of 20 children, all of whom showed positive Dick tests, received an intramuscular injection of 2½ c.cm. of B. W. and Co. concentrated antitoxin (A. 4488r). Of these 50 per cent. became Dick-negative within 24 hours of the injection, and, taking seven days as the longest incubation period of scarlet fever, it was found that 30 per cent. remained Dick-negative for that length of time (Dick toxin × 48, B. W. and Co.). A dose of 5 c.cm. of the same type of serum (A. 4488r) was next employed on 25 Dick-positive reactors: 48 per cent. became Dick-negative 24 hours later and 56 per cent. within 48 hours of receiving the injection. They all remained negative for seven days (Dick toxin × 48, B. W. and Co.).

A further series of 20 children were given 5 c.cm. of P., D. and Co. concentrated antitoxin (079761B). Of these 70 per cent. showed a negative Dick test 24 hours later and 95 per cent. within 48 hours; subsequent tests proved that 95 per cent. of this series remained Dick-negative for the required seven days. (Dick toxin B. 3015, B. W. and Co.)

The material used for performing the Dick tests in the last two series of cases differed, as shown by the contr-

numbers, and it was thought that this might partly account for the variation in results obtained.

Finally I administered 5 c.cm. of B. W. and Co. concentrated antitoxin (A. 4608A, A. 4608C) to 22 children and used toxins (B. 3782 and B. 3812, B. W. and Co.) for the Dick tests. In this group 60 per cent. became Dick-negative 24 hours later, but only 50 per cent. remained so for seven days.

All these tests were performed upon diphtheria-convalescent patients, and the serum and Dick toxin employed was always used shortly after receipt from the makers.

An opportunity to employ scarlet fever antitoxic serum prophylactically was afforded on two occasions when a case of scarlet fever developed in a diphtheria ward. The procedure adopted was to Dick-test all the contacts, and on the next day to give to those showing a positive Dick test and negative control an intramuscular injection of 5 c.cm. of concentrated scarlet fever streptococcus antitoxin.

CASE 1.—Out of a total of 17 contacts 11 were Dick-positive (Dick toxin B. 3888, B. W. and Co.). Of these only two showed a negative Dick-test 24 hours after the injection of serum (A. 4654B, B. W. and Co.). One of the children who received serum and who remained Dick-positive developed scarlet fever ten days after the primary case had been isolated. This case, developing beyond the longest incubation period of scarlet fever, cannot be regarded as having been infected from the primary source.

CASE 2.—Amongst 15 contacts there were seven Dick-positive reactors (Dick toxin B. 4084, B. 4126, B. W. and Co.), and these were given 5 c.cm. of antitoxic serum (A. 4661D, B. W. and Co.). All of them showed a negative Dick test 24 hours later, and the test remained negative for ten days. No secondary cases of scarlet fever developed.

As the infecting cases in these two outbreaks were promptly isolated the absence of secondary cases is not surprising, and therefore the serum must not be given too much credit.

The views of various workers on the efficient therapeutic dose of antitoxin for cases of simple scarlet fever have differed. The general opinion seems to be that an amount of antitoxin equivalent to 200,000–1,000,000 skin-test doses of scarlet fever toxin fulfils the requirements for cases of average severity.

Each patient in the series of 500 cases of simple scarlet fever received the recommended dose of 10 c.cm. (B. W. and Co. antitoxin being administered to 293 cases and P., D. and Co. serum to the remaining 207). The injection was, in every case, intramuscular into the lateral aspect of the thigh. The ten cases of septic scarlet fever were treated by an intramuscular injection of 10 c.cm. of concentrated scarlet fever streptococcus antitoxin followed by 50–100 c.cm. of polyvalent antistreptococcal serum (B. W. and Co.). The therapeutic dose of 10 c.cm. was repeated 12 hours later in both the cases of toxic scarlet fever.

Results of Serum Treatment.

I propose to summarise separately the results of serum treatment in the three types of the disease under consideration—viz., simple, septic, and toxic scarlet fever.

TABLE I.

S = Serum-treated case.

C = Control case.

Simple Scarlet Fever.—Table I. shows the age-groups of the serum- and non-serum-treated or control cases and the day of disease on which the patients

were admitted to hospital. All patients received their injection on the day of admission. The control cases were treated on purely symptomatic lines.

In evaluating the effects of antitoxic serum I wish to draw particular attention to the following salient points in the clinical course of the disease: (1) temperature curve; (2) nervous manifestations; (3) duration of rash and degree of desquamation; (4) serum reactions; (5) incidence of subsequent complications; (6) duration of stay in hospital; (7) incidence of relapses and second attacks; (8) case-mortality.

Temperature Curve.—In cases of simple scarlet fever the temperature normally falls on the third to fifth days of disease, irrespective of serum treatment, and so it is difficult to ascribe reduction of pyrexia, unless very dramatic, to the effects of serum. Table II. shows the course of the temperature in the serum-treated and control cases.

TABLE II.

Total ..	52	52	241	241	185	185	22	22	500	500

Nervous Manifestations.—The toxin of scarlet fever apparently acts as an exciting factor to the nervous system, whereas that of diphtheria is a depressant. Practically all the cases to whom serum was given on the evening of admission to hospital showed marked improvement in the toxæmic manifestations of the disease within 12 hours. This was most easily judged in adult patients, who invariably admitted that they felt much more comfortable and relatively well within a short time of receiving treatment.

Effects on Rash and Desquamation.—The rash is regarded as due to the toxin of the causal organism, and so it is to be expected that the prompt administration of the specific antitoxin will cause a blanching of the exanthem before its normal time of disappearance. This phenomenon is most strikingly seen in the early rashes of under 48 hours' duration; complete blanching occurred in 60 per cent. of cases within 24 hours. In some cases the rash showed little or no blanching beyond normal limits. This fact may be ascribed to inadequate dosage or to lack of specificity on the part of the antitoxin towards the toxin elaborated by the particular strain of hæmolytic streptococcus. Moreover, rashes of over 48 hours' duration become stained into the tissues of the skin and cannot be blanched by the antitoxin. As was to be expected, the cases showing complete or modified blanching of the rash had an almost imperceptible desquamation.

Serum Reactions.—According to previous observers the introduction of concentrated preparations of serum has resulted in diminished frequency and severity of reactions. Out of the total of 500 cases receiving serum, 41 per cent. showed reactions at periods varying from 4 to 16 days after the injection. In no case did the symptoms give rise to alarm. In 25 per cent. of these cases there was only a rash—usually urticarial in nature—which lasted from a few hours to three days in the most severe cases. The remaining 16 per cent. showed definite signs of serum disease: slight pyrexia, adenitis, fleeting joint pains, and an urticarial eruption.

Calcium chloride was given orally for ten days after the serum injection in doses of grs. 5 to children and grs. 10 to adults thrice daily. It was found to have no

effect at all in reducing the number or intensity of the reactions.

Incidence of Subsequent Complications.—The power which an antitoxic serum possesses of preventing or reducing the various complications associated with scarlet fever forms the main line of investigation of the therapeutic value of such a measure. Most workers agree that serum, even when given on the first day of disease, is not an absolute safeguard against complications. A comparison of the incidence of complications in 500 cases treated with serum and a similar number of control cases is given in Table III.

As the table shows, the complications in cases not receiving serum until the fourth day of disease were more numerous than in the control series, and the best results were obtained amongst cases treated on the first day of disease. The table shows that the number of multiple complications in the control cases was

TABLE IV.

Complications.	S.	C.
Arthritis ..	7	19
Nephritis ..	1	6
Otitis media ..	40	54

twice that in those treated with serum. The incidence of arthritis, nephritis, and otitis media in cases treated with serum during the first three days of disease and in a corresponding number of control cases is shown in Table IV.

Arthritis occurred chiefly in adult female patients; and the likelihood of its being a serum phenomenon was, as far as possible, carefully excluded. The nephritis was an extremely mild type and occurred in a female aged 12 who received serum on the third day of disease.

Duration of Stay in Hospital.—The usual quarantine period of four weeks for simple, uncomplicated cases of scarlet fever was not altered for serum-treated patients, and if there were complications the cases were detained in hospital until clear of infection. Fresh complications developed after the fourth week of disease in 14 serum-treated patients who had already shown complications, except one who was discharged as a clean case at the end of the fourth week and who was readmitted one week later with a purulent rhinitis and otitis media. The number of weeks in hospital beyond the usual quarantine period was 485 for the 500 serum-treated cases, while for the control series the figure was 680 weeks.

Incidence of Relapses and Second Attacks.—The serum-treated cases showed three genuine relapses during the fourth week of the disease, an incidence of less than 1 per cent., which cannot be regarded as exceeding normal limits. Second attacks of scarlet fever, though rare, do occur, and a girl of 5 who received her injection on the second day of disease had a second mild but quite definite attack nine months later. The Dick test on the second day of disease was negative, which suggests that the particular strain of hæmolytic streptococcus causing the second attack differed from that causing the primary disease.

Case-mortality.—The case-mortality for simple scarlet fever is at present very low, owing to the mild type prevalent in this country. It is therefore difficult to imagine that serum therapy will cause any dramatic change in this. One death occurred in the serum-treated cases, and was attributable to an intercurrent tuberculous peritonitis. There was also one fatal case in the control series.

Septic Scarlet Fever.

It was hoped, by the combined administration of the two types of serum—concentrated scarlet fever streptococcus antitoxin and polyvalent antistreptococcal serum—to bring about improvement simultaneously in the two aspects of infection—viz., the specific hæmolytic streptococcus of scarlet fever and the secondary invading organisms. The effects have been observed on ten cases of septic scarlet fever. The number is too limited for definite conclusions, but the opinion formed of its efficacy is favourable. The cases were all of a very severe type with marked constitutional symptoms and exaggeration of the faucial condition, together with cervical adenitis and purulent rhinitis. Six, after a febrile period varying from 3–12 days after the injection of serum, experienced an uninterrupted convalescence and were discharged from hospital during the fifth week of disease. Three developed otitis media, and in one of these the condition proceeded to mastoiditis requiring operation. They were discharged from hospital at the end of 9, 9, and 15 weeks respectively. The remaining child developed broncho-pneumonia during the fifth week of disease and remained in hospital until the end of the ninth week of disease. There were no deaths.

Toxic Scarlet Fever.

It is in this type of the disease that we look for the most dramatic results of specific serum therapy, if given in sufficient dosage and early enough in the course of the disease, when the patient has the power to respond. The two following cases, which may be regarded as genuine examples of toxic scarlet fever, were treated with concentrated scarlet fever streptococcus antitoxin.

CASE 1.—Female, aged 7, admitted to hospital on second day of disease. Three more cases of scarlet fever from same family. Temperature, 103° F.; pulse-rate, 108; respirations, 36. Pulse soft and thready. Rash poorly developed.

Lips cyanosed. Fauces congested. Severe vomiting and diarrhoea. Extreme restlessness. 10 c.cm., P. D. and Co., antitoxic serum given intramuscularly on admission. Very little improvement in general condition 12 hours later. 10 c.cm. of same type of serum given intravenously in half a pint of warm sterile normal saline. Very marked improvement 12 hours later. Vomiting and diarrhoea ceased. Restlessness gone. Temperature and pulse-rate reached normal 24 hours after second injection. No serum reaction. Convalescence uneventful. Discharged from hospital on the thirty-seventh day of disease.

CASE 2.—Female, aged 10, admitted to hospital on the third day of disease. Temperature, 103° F.; pulse-rate, 156; respirations, 32. Poorly developed punctate erythema over trunk. Tongue and fauces typical of scarlet fever. Slight cyanosis of lips. Pulse rapid and soft. Extreme restlessness. Marked diarrhoea. No vomiting. 10 c.cm., B. W. and Co., antitoxic serum given intramuscularly on admission. No definite improvement 12 hours later. 10 c.cm. of same type of serum given intramuscularly (attempt at intravenous administration failed). Marked improvement 24 hours after second injection. Restlessness and diarrhoea ceased. Temperature and pulse-rate normal 48 hours after second injection. No serum reaction. Convalescence uneventful. Discharged from hospital on the thirty-fourth day of disease.

Conclusions.

1. The potency of different samples of scarlet fever streptococcus antitoxin has, up to the present time, varied considerably as shown by the methods in use for testing its antitoxic titre.
2. A minimum of 5 c.cm. of the average serum at present on the market should be administered as a prophylactic dose.
3. The administration of antitoxic serum within the first three days of disease produces a favourable effect in counteracting the specific toxæmia.
4. The reactions following the administration of a reliable concentrated antitoxin are not severe.
5. An amount of antitoxin sufficient to neutralise 500,000 skin-test doses of scarlet fever toxin should be regarded as the minimum therapeutic dose for simple scarlet fever.
6. The full therapeutic dose should be given at the earliest possible moment to obtain the best results.
7. When given within the first three days of disease it lessens the incidence and reduces the severity of subsequent complications.
8. The therapeutic efficacy of the serum diminishes with each day of delay in its administration, and beyond the third day of disease it seems to have little effect in influencing the incidence of subsequent complications.
9. From the results obtained it does not seem advisable to reduce the quarantine period to less than four weeks in cases treated with antitoxin, but the total period of hospitalisation is reduced because the serum therapy lowers the incidence and severity of complications.
10. Antitoxin treatment of scarlet fever does not appear to increase the incidence of relapses beyond normal limits.
11. There is reason to believe that the treatment of septic scarlet fever by a combination of specific antitoxic serum and polyvalent antistreptococcal serum cuts short the course of disease and lessens the liability to the development of subsequent septic complications.
12. Specific antitoxic serum, if given early and in large doses, is an extremely efficacious treatment for toxic scarlet fever. Intravenous administration is more advantageous than intramuscular, as it ensures a more rapid maximum action.

I wish to take this opportunity of expressing my grateful thanks to Dr. W. T. Benson, medical superintendent, Edinburgh City Fever Hospital, for his kind permission to carry out these investigations and for much useful help.

WEST END HOSPITAL FOR NERVOUS DISEASES.—About £8000 was raised at the jubilee dinner of the hospital held at Grosvenor House last week in response to an appeal for £10,000 for development work.

Clinical and Laboratory Notes.

A CASE OF CONGENITAL VALVULAR OBSTRUCTION OF THE URETHRA.

By HELENA B. KING, M.B. LOND.,
MEDICAL OFFICER TO MATERNITY AND CHILD WELFARE CENTRE,
BRENTFORD;

AND

W. P. H. SHELDON, M.D., M.R.C.P. LOND.,
JUNIOR PHYSICIAN TO THE CHILDREN'S DEPARTMENT, KING'S
COLLEGE HOSPITAL; LATE MEDICAL REGISTRAR, HOSPITAL
FOR SICK CHILDREN, GREAT ORMOND-STREET.

THE condition of congenital bilateral hydronephrosis together with dilatation of both ureters is comparatively well known, but any example which helps to shed a light upon the pathogenesis of this condition is worth recording and considering from every available aspect. The following case is one of the youngest recorded, and the facts noted during the 20 days of life were checked and correlated at the post-mortem examination.

A primipara, aged 34, had a normal pregnancy until the thirty-fourth week, when slight cedema of the lower extremities developed and the urine contained a trace of albumin. The cedema was progressive until delivery, although no signs of toxæmia could be found, and the

FIG. 1.

Showing the whole urinary apparatus. Both kidneys are hydronephrotic, the ureters are dilated and tortuous, the bladder wall is hypertrophied, and the prostatic urethra is dilated.

systolic blood pressure remained steady at 130 mm. of mercury. The presentation was a persistent breech with extended legs, and delivery was by Caesarean section at full term. The mother had no pyrexia, and convalescence was uneventful. At the time of the operation it was noticed that there was practically no liquor amnii. Although the membranes had ruptured earlier in the day only a normal quantity of liquor had been lost during the few hours of labour that preceded delivery.

The child was a well-developed male, weighing 8½ lb. The scrotum and penis were very cedematous, and there was a well-marked right-sided torticollis, and a linear discoloration amounting almost to an abrasion of the skin of the subclavicular region where the head appeared to have been pressed closely against the chest wall. The child cried well, but from the first he seemed lethargic and took the breast

with difficulty. He never vomited. The cedema of the scrotum and penis subsided slowly, but the abdomen remained very distended. During the first 24 hours he was reported not to have passed urine and after that it was noticed that micturition was never in a continuous stream but drop by drop and accompanied by quite definite straining. Phimosia was not present nor was there any pinhole condition

FIG. 2.

* Microphotograph (low power) of a portion of the right kidney, showing a great excess of fibrous tissue, with a varying degree of dilatation of the tubules.

of the meatus, but all methods to promote the flow of urine failed, and by the eleventh day, although there was practically no cedema, the distended bladder could be felt between the pubes and the umbilicus.

On the twelfth day Mr. Neil Sinclair saw the child, and after passing a No. 1 gum-elastic catheter he drew off 2½ oz. of urine. The first two inches of catheter entered without much difficulty, but then it appeared to be gripped as though by a muscular spasm, and the obstruction was only overcome by maintaining steady pressure for a minute or two. He diagnosed obstruction in the prostatic urethra, probably valvular, and advised regular catheterisation in the hope of breaking it down mechanically. Whatever the nature of the obstruction, it allowed the passage of a catheter into the bladder, yet acted as a barrier to the outward flow of urine. The difficulty of catheterisation became more marked with each attempt. For three days a catheter was passed, but on the three succeeding days all efforts to overcome the obstruction failed, and the child became very limp and drowsy. As the bladder remained obviously distended, Mr. Sinclair again saw the child, and succeeded in drawing off 3 oz. of blood-stained urine through a ureteric catheter. In spite of the frequent catheterisation there was no improvement in the rate of micturition; urine was still passed drop by drop and continued to contain blood. On the nineteenth day the bladder became harder, and was the size of a tangerine orange. The ureteric catheter was passed, but no urine could be obtained. The child was by now in a uræmic state, and became convulsed that evening. Death took place 12 hours later.

Post-mortem Examination.

The external appearance of the body was normal except for the unusual size of the abdomen. There was no cedema. When the abdominal cavity was opened free blood-stained fluid was found and petechial hæmorrhages were scattered over the visceral and parietal peritoneum. The kidneys, ureters, and bladder, with about two-thirds of the urethra, were dissected out and removed entire, the symphysis pubis being divided to facilitate the dissection of the urethra to a point beyond the site of the supposed obstruction (Fig. 1).

Kidneys.—Both kidneys were enlarged, and their surface was studded with numerous transparent cysts ranging in size from a pin's head to a large pea. The left kidney measured 8 × 4½ cm. and the right 6 × 3½ cm. Both were definitely enlarged. The capsule stripped with difficulty, being tough in places and adherent, and the surface of the underlying kidney was covered with numerous pin-head cysts. The pelvis was very dilated, and the calyces extended almost to the edge of the kidney substance, forming wide pockets and reducing the renal tissue to a narrow rim 2 mm. thick. The terminal ramifications of the pelvis seemed to have no communication with the cysts on the outer surface of the kidney, suggesting the possibility of a concurrent polycystic condition in addition to the hydronephrosis. Microscopically the most remarkable feature of the kidney was the great excess of fibrous tissue throughout. For the

most part this was arranged in whorls around small islands consisting of three or four small tubules. In other areas it enclosed large cystic spaces consisting of dilated tubules. Only a few glomeruli could be discerned, and these had undergone hyaline degeneration (Fig. 2).

Ureters and Bladder.—Both ureters were enormously dilated, resembling small intestine, and were doubled upon themselves in a series of S-shaped curves, the actual length being thus about double the apparent length. Their width was 1 cm. The bladder was the size of a tangerine orange, and showed great but uniform hypertrophy of its musculature. The muscle wall measured 1 cm. in thickness, but there was no special thickening to indicate a sphincter. The mucosa was corrugated, and there was an intense hæmorrhagic cystitis which ceased at the trigone. The ureteric orifices were closely contracted.

Urethra.—The verumontanum was well developed and showed a longitudinal groove down its centre. In the normal infant the ridge of the verumontanum gradually fades out on the floor of the urethra, but in this case the verumontanum was prolonged forwards, diverging into two prominent ridges covered by mucosa, which eventually fused with the roof of the urethra. The channel of the urethra on the outer side of the two ridges of the verumontanum thus ended in a blind cul-de-sac. Stretching between the two ridges was a thin loose membrane or valve, attached at its distal end to the roof of the urethra. At the point where the verumontanum forked into the two ridges there was a small opening through the membrane, through which urine in the prostatic urethra could pass down under the membranous valve into the penile urethra. Because of its laxity the membrane actually lay on the floor of the urethra between the ridges of the verumontanum. An entering catheter could raise up the membrane and pass through the small opening into the prostatic urethra, but considerable force would be required to expel urine down through the opening into the penile urethra (Fig. 3).

Discussion.

The thin curtain of tissue at the level of the verumontanum was clearly a developmental fault, and must have been present from the earliest weeks of foetal existence. The secondary changes which resulted from the valvular obstruction—such as the great hypertrophy of the bladder muscle, the increase in length and width of the ureters, and the dilatation of the renal pelvis with extreme diminution of the functioning kidney tissue—cannot conceivably have developed during the 20 days of life.

Their production must have begun during, at any rate, the later stages of intra-uterine existence, and they argue some considerable effort by the foetus to micturate. The muscular development of the bladder was such that, when exerted to its utmost during life, the valvular obstruction could be partially overcome and a small proportion of the urine expelled. That this was never without great difficulty was shown by the interrupted flow and the abdominal straining that accompanied micturition.

FIG. 3.

A closer view of a small part of the bladder and of the urethra. There is a hæmorrhagic cystitis down to the inter-ureteric bar. At the distal end of the verumontanum can be seen the valve formation, under which a short stilette has been passed.

The hypertrophy of the bladder and the dilatation of the ureters seem to have been purely a response to prolonged mechanical obstruction. The kidneys formed the final barrier and sustained the greatest damage. The kidney-substance had atrophied almost to non-existence, and had undergone profound fibrosis. The cystic distension of some of the tubules was presumably due to partial or complete obliteration of some portion of the lumen, preventing the normal passage of urine out of the tubule.

The case may shed some light upon the pathogenesis of congenital cystic disease of the kidney, for the condition of the kidneys was closely comparable to congenital cystic disease, the cystic condition being the result of an intra-uterine renal fibrosis. Further, in this case the fibrosis of the kidneys was secondary to an organic structural defect in the urinary apparatus.

The small amount of functioning kidney-substance would certainly have proved inadequate to meet the demands of the growing organism, and the infant would appear already to have been suffering from toxæmia due to inefficiency of renal function from birth onwards, as evidenced by its abnormal drowsiness and lethargy, culminating in the uræmic convulsion just before death. The extent of the pathological changes in the urinary tract suggests that their formation commenced during intra-uterine life, probably from the time when urinary secretion first became a function of the foetus. Bearing in mind that this urinary output was considerably impeded, it is of interest to recall the fact, noticed at operation, that the liquor amnii was unusually diminished in amount. The functions of the amniotic fluid are still not entirely understood, but the presence in it of urea and other urinary constituents is generally assumed to denote some connexion between it and the urinary excretion.

In America H. H. Young, W. A. Frontz, and J. C. Baldwin¹ have fully investigated the formation of congenital valves in the urethra, and have operated with success upon some of these cases. In a recent communication by F. J. Poynton and one of us² the clinical symptoms to which this condition may give rise were described, and attention was drawn to the ease with which it may be overlooked at post-mortem examination. In the various examples there recorded of dilatation of the bladder and ureters due to some organic obstruction, infection of the urinary tract had invariably taken place by the time the child was brought for treatment. The onset of the infection may be sudden, but it generally persists for months or years before the patient succumbs. It follows that those instances of "pyelitis" in childhood which do not respond satisfactorily to treatment, but pass insidiously into a chronic or relapsing form, should be submitted to the most careful investigation, with the aid of cystoscopy and pyelography, in an attempt to discover whether there is any remediable congenital deformity of the urinary organs.

The longer the individual survives, the more are the direct secondary results of the deformity obscured by the features of bacterial infection, until it becomes very difficult to say which is the cause of the changes found in that part of the urinary tract furthest removed from the site of the deformity. Hence it is important to investigate thoroughly every case of abnormality of the urinary tract, especially in its earliest stages.

Conclusion.

The case recorded shows a gross abnormality of the whole urinary tract, and in view of the absence of bacterial infection as one of the causal factors, we consider that all the changes in the urinary tract were due to the congenital valvular deformity of the urethra.

Our thanks are due to Miss Geraldine Barry, F.R.C.S., whose skilful post-mortem examination

facilitated further investigation of the case, and to Dr. J. G. Greenfield, who kindly made the micro-photograph.

GASTRIC SECRETION IN PHTHISIS.

By C. O. S. BLYTH BROOKE, M.R.C.S. ENG.,
D.P.H. LOND.,

CHIEF TUBERCULOSIS OFFICER, CITY OF STOKE-ON-TRENT;
FORMERLY ASSISTANT MEDICAL OFFICER, KING GEORGE V.
SANATORIUM, GODALMING.

It is commonly believed that in most cases of pulmonary tuberculosis the gastric secretion of hydrochloric acid is diminished. Knud Faber¹ stated in a recent lecture that achylia occurs in 33 per cent. of cases.

The work reported in this article was undertaken to verify this theory if possible, for a lack of digestive juices, if it exists, should surely be an indication for treatment in practically all cases of this disease. However, an investigation of the literature does not show any such general agreement with these ideas as some writers lead us to believe, and in fact several workers, such as Einhorn,² report that they have found hyperacidity in many, especially early, cases. Vague indigestion is the common lot of many phthisical patients, who have been described epigrammatically as potential dyspeptics. Probably indigestion is less common now that the older treatment of forcing food is rarely carried out; it was probably more often due to the "cure" than to the disease. Nevertheless, everyone working in this department must realise that these patients are more than normally subject to digestive disturbances. The frequency of indigestion as a symptom varies greatly, to judge from figures that have been published. For example, one author³ states that in 17 per cent. of male and 72 per cent. of female patients the earliest sign of phthisis is dyspepsia, while others have given such figures as 94 per cent.,⁴ 64 per cent.,⁵ and 53 per cent.⁶ The form of the dyspepsia varies, but the principal symptoms are fullness, flatulence, and pain, often, however, amounting to little more than a vague discomfort.

In 80 consecutive cases of early male adult pulmonary tuberculosis admitted into King George V. Sanatorium, Godalming, into whose history a special inquiry was made for the previous existence of digestive symptoms, the following percentage incidence of the various symptoms was discovered:—

No digestive symptoms of	Vomiting	..	2
any kind	Heartburn	..	1
Flatulence	Bad taste in mouth	..	1
Fullness	Migraine	..	1
Indefinite pains			9

These numbers indicate that the incidence is not very high, but a series of test-meals was conducted in order to determine whether or not the indigestion was associated with altered gastric secretion. The test-meal was that recommended by Ryle and now in common use—that is to say, the ordinary fractional test-meal after the ingestion of gruel. Specimens were examined for free hydrochloric acid and total acidity at the commencement of the examination and after 15 minute intervals, up to eight or more specimens.

Classification of the Titrations.

	Free hydrochloric acid.*	Total acidity.*
Normal	20–40 c.cm.	40–60 c.cm.
Hyperacidity	More than 40 c.cm.	—
Moderate hypo-acidity	11–20 c.cm.	—
Marked	Less than 11 c.cm.	Less than 25 c.cm.

* Both expressed as the equivalent of 100 c.cm. in terms of decinormal alkali.

According to all observers, there is a very wide range of normality, and in a series of 100 normal persons readings well below and well above the

¹ Jour. Urol., 1919, iii., 289.

² Poynton, F. J., and Sheldon, W. P. H.: Arch. Dis. in Childhood, 1927, ii., 251.

average—i.e., the figures obtained from 80 per cent.—will be found in several cases. I have adopted the above classification of the titrations for the purpose of convenience.

Twenty-one cases showing no digestive disturbance whatsoever were investigated. All were male adults and early but proven cases of phthisis. The following results were recorded:—

	Per cent.		Per cent.
Normal ..	62	Marked hypo-acidity	10
Hyperacidity ..	10	No free hydrochloric acid	..
Slight hypo-acidity ..	5	acid ..	15

Although there is a slight tendency towards hypo-acidity the figures are, on the whole, not very widely divergent from those of a similar series of normal individuals.

Of 18 cases with symptoms of indigestion, 77 per cent. were normal and 23 per cent. showed hyperacidity. It is to be noted that there were no cases with decreased acid-secretion. If it is possible to form conclusions from such a short series this suggests that diminution of gastric secretion is not part of the picture of early tuberculosis in men, and that when symptoms of indigestion arise, whether prominent or not, they do not necessarily indicate lowered acid secretion. These results agree in the main with those of Fairfield Thomas,⁷ who reported on analyses made along similar lines on the gastric secretion of 27 cases of pulmonary tuberculosis in varying stages. Theories of chronic gastritis, anemia of the gastric mucosa, or even ischaemia of the whole digestive tract which purport to account for an altered secretion are merely guesses based on indefinite and probably fallacious data. Gastric and duodenal ulceration are associated as a rule with hyperchlorhydria, and if pulmonary tuberculosis were associated with hypochlorhydria (using these terms in a loose sense), the two lesions should be combined extremely rarely in any one patient. This is not so, for in every large institution for the tuberculous a certain percentage suffer from ulceration. Moreover, phthisis in a sufferer from either of the previous diseases does not necessarily produce any favourable effect on the gastric condition. I was recently in charge of a patient, under treatment for an active focus in his lungs, who died from hæmatemesis and melæna, proved at autopsy to be from a gastric ulcer. I do not believe this was a very exceptional case.

Acid Therapy in Phthisis.

Hydrochloric acid was given to a series of 24 cases, selected at random, of those suffering or who had suffered from indigestion and to those who had never, even on careful inquiry, given any history of such symptoms. It was thought that if an appreciable number of these were suffering from a lack of gastric juice they might, on its partial and artificial replacement, show some sign of improvement in general health, especially on their weight charts. Of these 24, one declared himself unable to take the acid; five, otherwise at a standstill, showed no change; ten, who were improving slightly, continued their improvement without any obvious acceleration; two appeared on the surface to go downhill after the administration of the acid; two appeared to show definite improvement (one of these had ultra-violet therapy at about the same time), and one stated that he felt very much better than he ever had previously, but examination of his charts and his physical signs showed no material change.

These results, therefore, do not encourage further investigation, for they tend to show that the reports in the early stages of phthisis of definite changes in the secretory response have been exaggerated.

I have to thank Dr. James Watts, under whose care these patients were, for his assistance, and for permission to publish the results.

SHOT IN THE VERMIFORM APPENDIX.

BY JOHN FRASER, M.C., CH.M., F.R.C.S. EDIN.,
REGIUS PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF EDINBURGH.

FOREIGN bodies in the vermiform appendix are relatively frequent findings, and numerous cases have been recorded in which the occurrence would seem to have played an important part in the subsequent pathology. Mahoney,¹ recording a case in 1921, in which a pin was discovered occupying the lumen of a child's appendix, reviewed the literature up to that date, and quoted observations on 81 cases, the earliest of which was dated 1840, when Houston,² of Dublin, discovered a foreign body in the appendix on post-mortem examination. Since Mahoney's paper was published records of 29 cases have appeared in

Radiogram of the appendix.

English and foreign literature. This total of 110 cases affords, of course, no true idea of the incidence of the occurrence, as it is likely that only a relatively small proportion of the total cases has been recorded.

An Unusual Case Related.

A few months ago a case in this category came under observation, and, as it presented some unusual and interesting features, it seems reasonable to record the details.

Mr. C., an active man of 51 years, complained of discomfort in the right lower quadrant of the abdomen. The discomfort was occasionally exaggerated into attacks of acute pain, which were short in duration and unaccompanied by any disturbance of temperature or general illness. There was no history of vomiting, constipation, or urinary disturbance. The appetite remained good and there was no discomfort after food, but the patient (a trained and shrewd observer) recorded the fact that the passage of flatus afforded temporary relief from the discomfort.

Abdominal examination was negative except for the fact that pressure immediately below and to the right of the umbilicus produced a certain degree of discomfort. In the history of the previous health the only positive feature was the record of recurring attacks of gout, dating from 1915.

X ray (barium meal) investigation was carried out in March, 1928, and the radiographer recorded the presence of small shot in the appendix; others who saw the plates were inclined to regard the appendicular shadow as being due to barium entering the lumen of the organ. As later events

showed, the observation of the radiographer was correct. The X ray findings, whatever the explanation, suggested an abnormal condition of the appendix, and operation was recommended in the hope that an appendectomy might relieve the symptoms.

Operation on April 24th, 1928, revealed an appendix 9.5 cm. long containing what appeared to be a great number of small shot. Later computation showed the actual number to be 48, and, with two exceptions, they were collected and cemented together in the distal half of the organ (see figure). The peritoneal coat of the appendix showed no trace of inflammatory change, and a later microscopical examination revealed no infection or reaction in the underlying layers. As far as could be ascertained, all the shot were uniform in size, and one pellet submitted to a gunsmith was classed as No. 6.

The post-operative course was uneventful, and it is satisfactory to record that the operation was successful in relieving the symptoms.

Certain Related Facts.

Such are the simple details of the case, but there are certain related facts which are of interest. "And thus the whirligig of time brings in his revenges," for the victim of this occurrence is a well-known sportsman and game shot. The figures in his game book total a number close upon 250,000, and, as the edict of the physicians who treated his gout forbade the use of butcher meat, there was a liberal consumption of game. It is evident that to this we may ascribe the remarkable collection which the appendix displayed, and that yet another "record bag" was added to the list. It may be that the ghost of some grouse will echo with Valentinian.³

"I love a dire revenge. Give me the man that will all others kill and then himself."

In a more serious vein, however, there is no doubt that the presence of this heavy collection of lead shot (one-seventh of an ounce) was responsible for the train of symptoms complained of—the dragging discomfort in the right side, and, as a result, of recurrent attacks of cæcal spasm, the more acute and short-lived pains. The appendix wall itself showed no sign of inflammatory reaction; in fact it was probably in some measure protected from infection, partly by the matter which occupied the interior and partly by the potential antiseptic properties of the contents, but its weight and the reflex disturbance which this engendered no doubt resulted in a mesenteric drag and its associated signs and symptoms.

One clinical point there was into which significance might be read, and one regrets that the matter was not more carefully noted—there was an area of cutaneous hyperalgesia, perhaps unduly prominent and corresponding to the skin distribution of the appendix. It seems possible that the irritation of the mucous surface by the foreign bodies instituted the reflex, for a similar observation has been made in connexion with threadworms in the appendix. Apart from secondary perforation of the appendix, one of the dangers quoted in connexion with foreign bodies is the development of a tumour. An example of this has recently been recorded by Thorek.⁴ In the present instance there was no trace of anything suggesting a cell reaction or degeneration, and it was evident that worse things than lead may gain entrance to or evolve within the lumen of the vermiform appendix.

It may be that a record of this kind adds little to the store of knowledge upon which our art accrues, but to me it was an unusual occurrence, and I said to myself "*rara juvant*."

STORNOWAY HOSPITALS.—Mr. T. B. Macaulay, of Montreal, President of the Sun Life Assurance Company of Canada, has within the past two years given nearly £20,000 to various institutions in Stornoway. He has now given £8000 to the endowment fund of the Lewis Hospital and with £12,000 capital money contributed by the Treasury, through the Scottish Board of Health, this should make it possible considerably to increase the efficiency of the institution.

Medical Societies.

MEDICO-LEGAL SOCIETY.

A MEETING of this Society was held on Nov. 22nd, with the President, Sir WILLIAM WILLCOX, in the chair. Dr. L. A. WEATHERLY read a paper on

JUVENILE PSYCHOLOGIC DELINQUENCIES.

He said that the study of human nature must go hand in hand with the study of the individual's mind, and physiology, pathology, and sociology must aid psychology. As Dr. J. Devon had said, "the only one principle in penology is to find out why the delinquent did wrong and make it not worth his while to do it again." Among a wealth of contributory factors one major cause could always be found. Criminal conduct was instinctive conduct and adapted to savage rather than civilised countries. Either the instincts and emotions were too strong for the intelligence, or the intelligence was too weak to control the instincts or emotions. The inherited disposition of these instincts might be for good or evil, and if they were allowed to run riot unsocial conduct must result. The causes bringing about lack of control over or accentuation of the worst features of instinctive emotional activities were complicated. Any physical ill-development might have this effect—for instance, defective sight or hearing and orthopaedic deformities. The late Mr. Thomas Holmes had been convinced that the most serious causes of crime were more physiological than psychological. Secondly came pathological causes—mental disease leading to crime. Dementia-præcox patients were subject to sudden inexplicable impulses, usually aggressive and destructive, yet to the ordinary observer the sufferers seemed normal and well-behaved. Dr. W. C. Sullivan had said that homicide was, par excellence, the crime of the epileptic. Encephalitis lethargica entirely altered the character of its young victims so that they took an absolutely immoral attitude to social life. They should be sent to an institution and never to prison. A peculiar pathological condition sometimes followed injuries to the viscera or abdominal operations; the character would alter and the youth might develop sexual perversions. Sometimes the alteration of sleep in change from day- to night-work would have a grave effect on a boy's emotional centres. Evidence of certifiable insanity in these pathological cases was rarely found, and some were tried and convicted without any defence or realisation of the cause of their criminal act. The present system of probation permitted appropriate care and treatment. The third group of causes was sociological. It was an error to suggest that every delinquent was the helpless victim of his inborn nature; there were many contributory environmental causes. Dr. Burt had concluded that poverty played only an indirect part and that there were more good children in the hovels of Hoxton than in the mansions of Mayfair. The sociological causes of crime were defective discipline, a family history of vice and crime, detrimental companions, excessive or inadequate amusement, lack of healthy pursuits, and defective family relationships. Cases of mental deficiency should be easily diagnosed and sent to institutions; it was a scandal that the institutional accommodation was so inadequate. The subnormal, however, was a much more difficult problem. Shuttleworth and Potts had described a class of case in which the strain of puberty produced a temporary lapse of moral sense. Prison was no good for these people, but tact, confidence, and kindness might make them good citizens. Most subnormals required something between Home Office schools and Borstal institutions on the one hand and simple supervision under a probation officer on the other.

Measures to Deal with Young Offenders.

Juvenile courts had been introduced in 1908, and children under 17 could now only be sent to prison

under exceptional circumstances. Reformatory schools and industrial schools—now called Home Office schools—had been reorganised, and probation officers were appointed to every court of summary jurisdiction in the kingdom. The report of the departmental committee appointed in 1925 was full of interest and excellent suggestions. It advocated juvenile courts in every court of summary jurisdiction, to be held quite apart from the police-court, and urged that three special magistrates should be appointed to each, one of the three being a woman. Coöperation between juvenile courts and education authorities was essential, and the help of psychology and psychiatry should be enlisted. The report suggested the establishment of hostels for probationers whose home environment was unsuitable, and called attention to the need of observation centres and remand homes—such as existed in America and had been described by Dr. R. G. Gordon in "Autolycus." Farm colonies were, in the speaker's opinion, the best kind of institution for subnormals, and occupational therapy should be the keynote of their treatment. Rate aid, voluntary contributions, and "self-help" (by the parents of the children) should be sufficient to maintain the colonies. Too many young delinquents still drifted into prison, and the reasons for this were financial stringency, bias on the part of magistrate or magistrate's clerk, and the dislike inherent in every individual to anyone but themselves putting their house in order. Finance should be dealt with on a basis of everyone doing their share, and bias should be eliminated by making the Home Office suggestions obligatory. The wonderful work done by voluntary effort must not be forgotten. There was too great a tendency to think things impossible before testing their possibility.

Discussion.

Earl RUSSELL agreed that in a great many cases delinquency was not so much a matter of conscious criminal intent as of some physiological, psychological, or environmental factor, and the one thing you should not do with young persons was send them to prison. That idea, however, permeated slowly to the country magistracy. The Home Office suggestions must, however, be administered with intelligence and sympathy, and not as a matter of routine because they were ordered. The best way to convince lawyers that the doctors were not "trying to get the better of them" was to show them the results of sending subnormal cases to suitable institutions.

Dr. T. B. HYSLOP thought on the whole it was worse for a child to be branded as of unsound mind than to be found guilty of an offence. The former was more far-reaching, passing down, as "insanity in the family" to the third and fourth generation, who feared, and indeed anticipated their trouble. The law must come to realise the existence of physiological explanations of offences.

Lieut.-Colonel C. T. SAMMAN said that a hundred years ago we hanged a man for stealing a sheep and now we gave him six months for diabolical murder; we were much too lenient with the juvenile offender. He advocated sterilisation of all criminals.

Dr. W. A. POTTS doubted whether, if all criminals were sterilised, there would be enough of us left to see the result of our experiment. Crime would not be stopped by making it "not worth the criminal's while," for often it was not worth his while already. Juvenile crime might be the result of ignorance and misunderstanding or misleading education. For instance, a child from a very poor home, where all the few possessions were common property, would not understand that the same conditions did not apply at school. A child who had seen its parents take what they liked from a shop, murmuring "Put that down to me," might find it very hard to see the difference when it went and took what it liked itself. Encephalitis lethargica was a very important cause of delinquency, and the initial attack was easy to overlook. The delinquency should not be looked on as an after-result, but as a later manifestation of a condition that was still active and that required full and adequate

treatment. The establishment of a juvenile court and a sympathetic magistrate was not going to solve the problem and "get at the mind of the child." That could only be done by heart-to-heart talks in private. It was most important that probation should be conditional and long enough. Young people were not sent to universities for three or six months, and when they had been misled and miseducated all their lives they needed still longer periods for education.

Mr. W. E. CHADWICK spoke of the importance of treating the child in the home at the "difficult" stage before it became delinquent. The real problem was to prevent delinquency and to find some way of teaching parents how to deal with these children.

Dr. R. G. GORDON pointed out that the child who came to the juvenile court was never a "first offender." Parents regarded a child who stole either as amusing or as something too dreadful to talk about. Parents must be taught to seek advice, and if that advice were to be given in the juvenile court there must be a change in its atmosphere. Alternatively there might be some kind of advisory clinic, such as that at Bath, which had proved very successful. The difficulty was almost always a failure of adjustment between the child and society; this ability to adjust was an important part of the personality about which too little was known. Simple mental backwardness was by no means the only cause of delinquency.

Dr. F. C. SHRUBSALL emphasised the difficulty the child had in adapting to town life. We could pick blackberries off a country hedge as much as we liked, but if a child took a blackberry from a basket in town it became a delinquent. There was a hundred times as much juvenile crime in America as in this country, but it was least in the Middle West, where the children lived an outdoor life and had more opportunity for games and exercise. The school and not the court was the place to stop crime; the increasing size of the schools had destroyed the personal contact between master and boys, so the clinic had to take its place. Only 10 per cent. of juvenile delinquency was due to ill-health or abnormality. The real old lag never did anything to corrupt a child; it was the boy a year or two older who was the danger.

Dr. LETITIA FAIRFIELD said that institutions were a very important part of social reform, but they were very expensive. A cheap institution was a nasty institution and would do its inmates no good. You could not make a home from home by calling it a colony, and so long as the child was forced to remain there he would long for home and the fried fish shops. The children were not delinquent because they were subnormal, but because the schools were not adapted to their mentality. The school had to deal with the average. The bright child, who ought to be pushing ahead, was quite likely to become a burglar, but he was better catered for than the subnormal, whose life was one continuous failure and snubbing and hopeless competition. The few gifts—often manual—of the subnormal child had no chance of development because he did not reach standard IV. or V., where there was a manual class. Much could be done to give him a world in which he could be happy if we would cater for him in our educational system. Another way of relieving his lot was through clinics. There was no wish to dodge punishment for children for whom it would do good. There was no kindness to a child in letting it think it could "get away with" crime. But unintelligent punishment had been tried again and again; history was littered with the cruel failures of that system. These children should be treated as we should like to be treated ourselves, and put in a position where they could exercise responsibility. They were struggling with a problem they could not understand and forces they could not control. If law rested on the intelligent consent of the governed the child who had been treated like that would surely be a better citizen and able to give something back to the law.

Lord RIDDELL said that if it was possible to change a child's mind and disposition by proper medical

treatment the first thing was to ensure that such treatment was obtainable, and the general practitioner ought to be trained to deal with these cases.

Dr. E. SLOAN CHESSEY emphasised the importance of motive, of the mother, and of decent housing.

Dr. WEATHERLY briefly replied.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

MATERNITY AND CHILD WELFARE GROUP.

THIS group held a meeting at the Royal Free Hospital on Nov. 23rd, Prof. LOUISE MCILROY, the President, being in the chair. A discussion on

ANTENATAL METHODS WITH SPECIAL REGARD TO DISPROPORTION

was opened by Mr. EARDLEY HOLLAND, who said that a weak point about the municipal antenatal clinic was that no beds were attached to it, and the doctor in charge did not look after the women during their confinement, so that an element of irresponsibility crept in. Public health authorities had given great prominence to antenatal work, but far more women lost their lives through lack of care during labour than through lack of antenatal care. The only way to establish a new standard in midwifery was to start with the medical profession, and the only way to do that was to set up more large maternity hospitals. Pelvic measurements had been decried, but they were valuable in giving an early idea of what sort of labour the patient was likely to have, so that everyone could be prepared, if necessary, for induction, Cæsarean section or hospital treatment. Vaginal examination had also been decried, but was important in that it enabled the practitioner to measure the diagonal conjugate and get some idea of the shape of the pelvic outlet. The importance of engagement of the head, on the other hand, had been exaggerated. In some 20 per cent. of primiparæ who had normal labours the head remained floating until the last week or even until the onset of labour. The mere fact of failure to engage was not sufficient evidence of disproportion or difficult labour. Disproportion could not be standardised; it was a matter of personal estimation, depending on an exact mental impression of what was right proportion. The reserve capacity of the pelvis played an important part. The normal pelvis was designed to take a 7½ lb. baby, but in fact it frequently managed a 10 or 11 lb. child by calling up its reserve capacity. Therefore the slightly contracted pelvis might reasonably be expected to manage the 7½ lb. baby.

The treatment of severe disproportion was inevitably Cæsarean section, but for the milder forms two alternative lines might be adopted; induction of premature labour, or test-labour at term and early Cæsarean section if it was apparent that natural delivery was unlikely. Induction was time-honoured, but the speaker said he had come to the conclusion that it was being done too often, since 80 per cent. of induced labours were far too easy. Induction was playing for safety; there were many unknown factors which, if favourable, might allow spontaneous delivery. If the foetus were premature the doctor must play for safety because the child would not stand difficult labour. Cæsarean section or craniotomy after induction was most dangerous.

Treatment by Test Labour.

In cases of genuine disproportion with a pelvis really contracted the decision was made at the thirty-sixth week, if necessary with the aid of a general anæsthetic. If there seemed a reasonable chance of spontaneous or forceps delivery at term the patient was allowed to go into labour and watched almost every hour. If after a few hours the head began to sink into the pelvis it would pass through; if not, Cæsarean section was performed. The decision required the highest skill and the method was only suitable for institutions with a resident accoucheur of

experience. Several secondary factors influenced the decision—e.g., premature rupture, posterior presentation, weak pains, and a nervous or unfit patient would indicate operation. Out of about 2000 deliveries at the London Hospital during the year there had been 17 cases of contracted pelvis, of whom 16 had had test labours. Eleven of these had had spontaneous delivery; three had had easy forceps and two early Cæsarean section. Only one baby had died. There had been no inductions at this hospital for two or three years.

Reducing the Size of the Head.

Dr. ANNIE MCCALL agreed that too many operations were done. She emphasised the fact that disproportion was between two things and there was a tendency to leave the second factor—the head—out of consideration. The size of the head could be altered by dieting the mother. Mothers who had received the advice they ought to have received during pregnancy did not have these enormous babies. During the last month—and preferably two months—the mother should have no protein—i.e., meat, egg, and milk should be forbidden. Milk made fat babies. She should be allowed as much fruit as she liked and should take plenty of hot water, sipping it by the half-pint. Equally important with diet was exercise during the same period. The woman ought to do three or four miles walking uphill daily. Erratic exercise was no good, and hill-climbing brought into play the muscles concerned in labour, which ordinary walking did not touch. Hot baths should be taken on alternate days during the eighth month and daily during the last month. They should be as hot as the patient could bear, and she should sit in them for 13 or 15 minutes. This softened the pelvic floor. Chloral hydrate, with or without bromide of potassium, was invaluable for softening the cervix and shortening the first stage of labour. Dr. McCall preferred to give it every other night for the last ten days before labour, and thought midwives ought most certainly to be allowed to carry the drug, as it saved untold suffering. She quoted statistics from the Clapton Maternity Hospital to show how effective these methods had been, and cited the "hymn" which was given to all the patients there:

In later months of pregnancy dispense with eggs and meat.
Then drink hot water freely; take fruit—all you can eat.
Hot baths are very useful, their value is untold;
These rules, with daily exercise, are worth their weight in gold.

Prof. F. J. BROWNE agreed that nothing required so much experience as the estimation of proportion and that the head might float without any pelvic contraction, but thought there was usually some other cause for the floating head—for instance, a posterior presentation or hydramnios. Constipation alone would keep the head out of the pelvis. He was at present quite satisfied with the method of induction; trial labour was not the practice at University College Hospital. He thought that the babies of premature labour often did not survive the first two or three years of life. "Playing for safety" seemed the one thing desirable in conducting a labour. Trial labour was impossible in private practice, but induction caused the doctor, the patient, and the relatives no anxiety and—provided it was not done before the thirty-sixth week—was perfectly safe for the baby. Treatment should never be determined before that week, but by then the head was hard enough to pass without injury through the maternal tissues. Since the date could not be ascertained with accuracy, the accoucheur should estimate the age by vaginal palpation of the head—the width and mobility of the sutures and the general hardness. There were two degrees of disproportion: first, where the head was just flush with the outer margin of the pelvic brim—it would then mould through well—and secondly, when there was definite overlapping, which contra-indicated induction; the case should then go to Cæsarean section at term.

The Significance of the Shape of the Pelvis.

Mr. ALECK BOURNE said that disproportion could only be defined after the baby was born. A case of disproportion produced a white, limp, toneless,

battered infant, with moulded head and large caput, and a perspiring accoucheur holding forceps. This sort of thing happened nearly always in one type of pelvis—the generally contracted. It was by no means the size of the pelvis that mattered most, but far more its shape. The generally contracted pelvis was not a small pelvis of normal shape, but an abnormal pelvis. The measurements were useful in giving an idea of the shape. Where the external conjugate was contracted and the sacrum of normal width, forming a roof over the pelvis, then the pelvis was a flat one and, if only a mild degree of flattening was present (as was usually the case in the south of England), then the head would come through. If all the measurements were reduced and the vaginal finger could feel the whole curve of the sacrum, which seemed to crowd down on the finger, that pelvis would give trouble. He recognised three conditions of the head: floating and refusing to be pushed down, floating and capable of being pushed in, and engaged. Overlapping should be estimated carefully. If it was just the thickness of the symphysis, so that the fingers would slide past it, then the head would come through. If it was overhanging it was dangerous. He was a whole-hearted inductionist: trial labour was impossible in private practice. No opinion should be given before the thirty-sixth week. "Pressing the head down into the pelvis" meant really leaning on the head, with both hands, from the shoulders, for some seconds. If it could not be induced to settle into the pelvis it would not come through, and Caesarean section was advisable. If it could be pushed in, labour should be induced two weeks later. The error of inducing too early after 36 weeks was very much less than the error of inducing too late and doing an unnecessary Caesarean section. After the thirty-sixth week an extra fortnight did not matter very much to the baby, always provided the labour was easy. If there was any doubt about the patient's having an easy time she should be induced on her date, and not a day later; she should not be allowed to go on from day to day in case she "came off to-day."

Mr. C. LANE-ROBERTS agreed that the date of induction should be settled and adhered to. He had found great benefit from dieting. Attempts to push down the head might fail without an anaesthetic and an enema.

Dr. MARY KIDD asked whether there was any hope of the oestrus-producing hormone providing a satisfactory method of induction. Bougies were impossible in many poor homes and quinine was most unsatisfactory.

Dr. E. H. NASH said that under no circumstances whatever would he allow anyone at an antenatal clinic to advise a midwife to induce labour. It was no part of the midwife's duty or the responsibility of any antenatal officer. It was an encroachment on private practice. Administrators were in great difficulties just now in trying to find the best thing for the mother, the midwife, and the practitioner, and for general peace all round. He had recently been asked at a British Medical Association meeting what specialists were required for at antenatal clinics, as it was work any general practitioner could do. Institutional accommodation was likely to be very limited for many years to come, and students must be taught the method they would have to practise, not what they could do in a hospital with everything at their fingers' ends.

Dr. MARION COCKERELL repudiated the suggestion that the doctor at the municipal clinic was in any way "irresponsible" because he did not see the case through labour. He heard far more about it all than the accoucheur, for he had to see the mother afterwards—with or without the baby.

Dr. AILEEN BOYD MACKAY further emphasised Dr. Cockerell's point and said she had found Dr. McCall's dietary very valuable.

Dr. A. NICOLL asked whether Dr. McCall had had any experience of the health and vitality of the babies after this dieting of the mother, and whether the diet affected the mother's power of uterine

contraction and of recovery. She herself reduced the protein, but tried to see that the mother had an adequate diet in other respects.

Dr. H. CHODAK GREGORY mentioned Dr. H. Mackay's work on anæmia in infancy, and asked where the baby was to get its iron reserve from if the mother was deprived of all protein.

Dr. ALAN HAMILTON described a type of illness in the early weeks of life and said how valuable it would be if the paediatrist knew what sort of labours the mothers of these children had had.

Dr. ETHEL CASSIE said that disproportion must be pretty rare in general practice, and asked whether it would be too Utopian to suggest that the few women who suffered from it should have routine institutional treatment, so that the measures taken for them were uninfluenced by considerations of private practice.

Dr. CHRISTIE BROWN agreed that the average practitioner saw only about 16 cases in a lifetime.

Mr. BOURNE, replying to questions, described investigations of quinine by the hystero-gram; the drug, when given in labour, destroyed the even sequence of uterine contraction and substituted for it a series of irregular, valueless contractions. It was quite useless for induction. Estrin might prove a solution of the problem, but was not yet sufficiently investigated.

Dr. G. C. M. M'GONIGLE spoke of the difficulties of antenatal work among a scattered northern population, often with out-of-work husbands unable to afford doctor's fees. The problem was largely financial, but for the present they must look forward to a large proportion of difficult labours.

Dr. McCALL said she thought the babies were better for the dieting.

Prof. McILROY said that it was barbarous to induce before the thirty-sixth week, and she rarely did it before the thirty-eighth. At the Royal Free Hospital inductions were usually at the thirty-ninth week or at term. She taught all her students as if the case occurred in an Irish bog, and not in a hospital. She had found a fair number of funnel-shaped outlets which the measurements of the brim did not reveal. In attempting to test the reserve force of the pelvis they had formulated a satisfactory test of the amount of "give" in the pubic arch. The patient stood on one leg and the examiner's finger under the pubic arch showed the range of its movement. In this way it was possible to know by the end of the pregnancy how the pelvis was going to behave during labour. She deprecated the custom of making the patients work hard during the second stage; they should take as much rest as possible and in this way much post-partum hæmorrhage could be averted. Dr. McCall's hot-water diet, after all, only forestalled the usual treatment instituted as soon as the patient showed any signs of toxæmia.

Mr. EARDLEY HOLLAND said he had pointed out that "trial labour" was only possible in an institution, but the time when most midwifery would be institutional was not far distant. There would be no midwifery salvation in this country until it came.

LEGISLATION ON SMOKE ABATEMENT.—We have already reported (*THE LANCET*, August 11th, p. 306) that at an inquiry held in July, 20 West Riding local authorities applied for confirmation of a by-law under the Public Health (Smoke Abatement) Act of 1926 with regard to the emission of black smoke from industrial chimneys. The Minister of Health has now replied that he will be prepared to sanction a by-law prohibiting the emission of black smoke for more than three minutes during a continuous period of 30 minutes. After trial of this by-law for three years he will be prepared to consider an application for the restriction to two minutes. The inquiry at Bradford has been regarded as a test, and the applications were the first of their kind under the Act. The by-law for which sanction was sought reads as follows:—

"That the emission of black smoke for a period of more than two minutes in the aggregate within a continuous period of 30 minutes from any building other than a private dwelling-house shall, until the contrary is proved, be presumed to be a nuisance."

Reviews and Notices of Books.

RECENT ADVANCES IN OBSTETRICS AND GYNÆCOLOGY.

Second edition. By ALECK W. BOURNE, B.A., M.B., B.Ch. Camb., F.R.C.S. Eng., Obstetric Surgeon to Out-patients, St. Mary's Hospital; Senior Obstetric Surgeon, Queen Charlotte's Hospital. London: J. and A. Churchill. 1928. Pp. 382. 12s. 6d.

THIS excellent review of progress in obstetrics and gynæcology has found an audience appreciative enough to call for an encore in two years, and the reason is plain. Sound judgment is shown both in the selection of topics and in the manner of their discussion, particularly in the obstetrical chapters. Antenatal care, the outstanding development in modern midwifery; the great and as yet unsolved problem of maternal mortality, and puerperal sepsis the largest and most difficult factor in that problem; the causation of foetal death; antepartum hæmorrhage and eclampsia form the subjects of six out of eight chapters and indicate the scope and practical nature of the book. The chapter on the chemistry of the blood and urine in pregnancy is a sound and judicial effort to appraise the results of biochemical research and coördinate them with clinical phenomena, so as to discover how far they can be relied on in diagnosis, prognosis, and treatment. It is a matter of regret that the author, whose pharmacological work on uterine stimulants is well known to our readers, has not seen fit to include a discussion on the causes of ineffective function in parturition—the most common reason for interference in labour—how they may be obviated and their effects modified by treatment. Recent years have seen more radical changes in principles in obstetrics than in gynæcology, and thus in the second half of the book attention is concentrated mainly on details in treatment, especially new procedures and technique, in the way of surgical operations, X rays, and radium. A new chapter has been added on the operative treatment of prolapsus, in which the methods of the Manchester School, as advocated by the late Prof. W. E. Fothergill, are first described and then the interposition and Mayo operations, the latter being illustrated from Ward's article in the recently published "Gynæcology" by Howard Kelly and collaborators. The scientific side of the specialty is represented by articles on endometrioma and a synopsis of recent work on "Ovarian Hormones," the latter giving a clear and reasonable presentation of a subject in which rapid advance is being made. The technique of radium therapy in cancer of the cervix is, save for a short paragraph on intra-abdominal applications, little altered from the previous edition and perhaps too much confined to the methods used by the author to fit into the scheme of the book as a broad survey of recent work.

For this second edition we predict as warm a welcome as that accorded to its predecessor.

GYNÆCOLOGY AND MIDWIFERY IN THE TROPICS.

Tropical Gynæcology. Clinical Lectures. By V. B. GREEN-ARMYTAGE, M.D., F.R.C.P., Lieut.-Colonel, I.M.S.; Professor of Obstetrics and Gynæcology, Medical College, Calcutta; Surgeon to the Eden Hospital, Calcutta. Calcutta and Simla: Thacker, Spink and Co. 1928. Pp. 249. Rs.3.8.

Tropical Midwifery. Second edition. Same author and publishers. 1928. Pp. 173. Rs.3.8.

THE author of the small volume entitled "Tropical Gynæcology" is well known to gynæcologists in Great Britain as an unusually gifted and enthusiastic teacher. He has given in the form of 11 clinical lectures some of his own experiences and findings in the course of 18 years' work at the Eden Hospital. It is addressed particularly to "new and even old comers in the field of oriental gynæcology, for in this

virgin field they will meet with conditions and clinical material that are practically never seen in the West to-day, and for which they may possess no reference or guide in the treatment." The book will, however, appeal to a far wider audience, for it includes chapters on such subjects as disorders of menstruation, sterility, prolapsus uteri, vaginal hysterectomy, and on gynæcological signs and symptoms. The chapter on obstetrics and gynæcology in the East is one of the best in the book, and impresses the reader by the variety of the problems that present themselves to the Indian obstetrician and by the wide differences that exist between practice in India and in England. Thus we read that a severe anæmia of pregnancy of unknown origin is extremely common (56 cases in four years in the Eden Hospital with a maternal mortality of 64 per cent.). Tetany, too, is of frequent occurrence as a complication either of anæmia of pregnancy or of osteomalacia. Eclampsia is common in the wet and cold months, and sufferers from it constitute from 3 to 4 per cent. of all hospital obstetrical cases; while contrary to what is frequently asserted, cancer of the cervix uteri is common and only about 7 per cent. of cases are discovered in the operable stage. To-day many general text-books of midwifery and gynæcology of the smaller type are being published. The time and energy consumed in their compilation would often be more usefully directed to preparing and publishing lectures of the kind before us, in which the writer deals with subjects of which he has had special experience, and can write from first-hand knowledge.

The title "Tropical Midwifery" is perhaps misleading, since the teaching is mainly devoted to the treatment of abnormalities which may be encountered in any climate though a few points of particular importance to those practising in tropical countries are mentioned. The work consists of 22 lectures delivered by the author at the Eden Hospital, Calcutta, and, considering its size, contains an enormous amount of useful practical advice. Prof. Green-Armytage's vast experience of obstetrics in the East has led him to give his own views on the treatment of abnormalities in a concise dogmatic manner. Wherever he disapproves of a recognised form of treatment he gives reasons for his opinion. In India, Cæsarean section gives much better results than induction of labour in cases of contracted pelvis on account of the increased risk of sepsis in hot countries. The lower segment operation has been adopted with success in cases which are potentially septic. The statement that in cases of placenta prævia the great dangers are sepsis and post-partum hæmorrhage is in accord with modern views on the subject.

The printing and paper are good; perhaps the use of heavy type to emphasise important points is rather overdone. Both of these small handbooks will be welcomed at home as well as abroad by practitioners and students.

SURGICAL DIAGNOSIS IN TABULAR OUTLINE.

By Dr. A. J. CEMACH, Vienna. Authorised translation with additions and notes by EDWARD L. BORTZ, M.D., Associate in Medicine, Lankenau Hospital, Philadelphia, Pa.; Assistant Instructor in Pathology, Medical School, University of Pennsylvania. Philadelphia: F. A. Davis Company. 1928. \$12.00.

THIS volume is a translation of a popular Austrian work on surgical diagnosis, and it is claimed that it is the only book of its type in English. The first edition of the Austrian publication appeared in 1914, and the present translation is from the fourth Austrian edition. The aim of the author, and of the translator, has been to deal with the whole subject of surgical diagnosis by means of tables and illustrations, and in this they have succeeded admirably. In some sections of the book this complete tabulation is a disadvantage, since it has made it necessary to provide several very large and complicated tables

It is difficult to see how the author could have avoided such a complication without altering the pattern of his book, and regarded as a whole the tables are excellent. There are altogether 100 of them, 87 dealing with regional surgical diagnosis and the remainder with general surgical diagnosis. The section on general surgical diagnosis is one of the best in the book; it contains clear and concise tables for the differential diagnosis of cutaneous ulcers, new growths of the skin, diseases of bursæ, and tumours of bone. The classifications adopted are entirely satisfactory, and in some cases have the additional merit of being new, thus providing the fresh outlook which is so essential for successful diagnosis. The American nomenclature, which is often quite different from that used in this country, is occasionally hard to understand. The author's meaning is usually obvious, but here and there it is impossible to correlate his expression with our nomenclature.

The illustrations form an excellent catalogue of surgical lesions, so far as these can be represented by pictures, and they are well arranged so that a table and the relevant illustrations can mostly be studied together. The original illustrations were made at the Crown Princess Stephanie Hospital in Vienna, and Dr. Bortz has supplemented them with others from the Lankenau Hospital. The portrayal of exaggerated types of the various lesions has been avoided, and good examples of a moderate degree of the condition illustrated have been chosen. The plates showing swellings of the abdominal wall, the different varieties of hernia, and ulcers of the skin could hardly be improved. It is unfortunate that the muscle selected to show hernia of muscle should have been the biceps brachii; the full-page illustration depicting this condition appears to be a typical example of rupture of the long head of the muscle. It would, however, be hypercritical to dwell on such small matters in a book which abounds in excellent illustrations. The reproductions of radiograms are good, and many clear and well-drawn diagrams are included, also an extensive bibliography.

The book can be recommended to surgeons and to students, for it will supplement the clinical teaching of the ward and out-patient department. It is printed neatly, and the binding is strong and durable.

DISEASES OF THE EAR, NOSE, AND THROAT.

Seventh edition. By WENDELL CHRISTOPHER PHILLIPS, M.D., formerly Professor of Otolaryngology, New York Post-graduate Medical School. Philadelphia: F. A. Davis Company. 1928. Pp. 922. 8s.

The new edition of this large work, which is a well-known standard text-book in the United States, is but little altered from the sixth edition, reviewed at some length in these columns (*THE LANCET*, 1923, i., 804). A chapter entitled the Hearing Problem has been added which deals in a helpful manner with the medico-social problems resulting from deafness. The section on otology occupies very nearly one-half of the volume, and abounds in those details likely to be of assistance to the practitioner. A new feature is a more complete description of the audiometer, which is now being used in the examination of school-children and, to an increasing extent, in consulting-room practice. The remaining portion of the book is divided into sections, respectively, on the nose and accessory sinuses, the pharynx and fauces, and the larynx, with a preliminary section on the influence of general diseases upon the ear, nose, and throat. This section includes tuberculosis and syphilis, with the result that these diseases in the larynx are discussed before the more general problems of inflammation have come under review. The use of the galvano-cautery in the treatment of tuberculous laryngitis receives no mention, although it is now the principal method of local treatment in England; in the chapters on the treatment of laryngeal cancer the operation of laryngo-fissure is still briefly dismissed with the statement that it "can rarely be

employed because it is applicable only to cases where the disease is limited to an extremely small area." In this country some considerable degree of success attends the efforts of laryngologists to obtain their cases while the disease is within reach of removal by laryngo-fissure. For the section on otology we have nothing but praise; by comparison with this, the chapters on diseases of the nose and throat show a lack of the practical first-hand knowledge and experience which distinguish the former section.

TECHNIQUE OF LOCAL ANÆSTHESIA.

Fourth edition. By ARTHUR E. HERTZLER. London: Henry Kimpton. 1928. Pp. 284. 25s.

The present edition of this classical work maintains the high standard of its predecessors, and is enhanced in value by the clearness and accuracy of its illustrations. It is noteworthy that the author is not enthusiastic about splanchnic injection. He quotes Meeker's 42 cases with the need for general anæsthesia in 18, and finds himself that "in conditions with dense adhesions splanchnic blocking does not secure a sufficient anæsthesia." We know no better guide to the use of local anæsthetics than Prof. Hertzler's book.

RENÉ THÉOPHILE HYACINTHE LAËNNEC.

A Memoir. By GERALD B. WEBB, M.D., President, Colorado School of Tuberculosis, Colorado Springs. New York: Paul B. Hoeber; London: Humphrey Milford, Oxford University Press. 1928. Pp. 146. 8s. 6d.

This is a reprint, with additions, of an article published in the *Annals of Medical History* (Vol. IX., No. 1, March, 1927) by Dr. Gerald Webb, who was the delegate representing the United States Government at the Laennec Centenary celebrated in Paris in December, 1926. Rouxeau's authoritative biography in two volumes is, we believe, not easily procurable in this country, so that the present work will be welcome to all medical men who care about the history of their science. Laennec had few advantages; his mother died while he was quite a boy, his spendthrift father married again, and his second wife did not take any interest in her stepson. Of feeble health, René Laennec was subjected to grinding poverty through all the early part of his life; he did not get enough to eat and he lacked proper clothing. In his early years he was much helped by his uncle, Guillaume-François, the physician of Nantes, and his own hard work brought its reward. It is surprising that he accomplished as much as he did, for he died at the age of 45 years.

The invention of the stethoscope in 1817 and the publication of "De l'Auscultation Médiate" in 1819 brought Laennec prominently before the profession. His work was adversely criticised by his contemporaries in his own land and progress was slow; but in spite of ridicule at home the reputation of the author quickly spread abroad, and foreign physicians crowded to Paris to hear Laennec before his untimely death in 1826.

The book is well printed and is enriched with 13 full-page plates.

MOTHER AND CHILD.

By MARY LYON. London: A. and C. Black, Ltd. 1928. Pp. 215. 5s.

This unpretentious little volume is designed for the use of mothers of the more educated classes. Mrs. Lyon, though not herself a medical woman, has founded her advice on the teaching of such experts as Dr. Eric Pritchard and Dr. Hector Cameron. Her book, which deals with the care of the child from its antenatal days up to adolescence, contains abundant hints of the most practical kind. The usual subjects—antenatal care, feeding, baths, exercise, weaning, and so on—are dealt with, but the author has managed to give her book a personal

character. Physical and psychical problems are discussed side by side with wisdom and sympathy, and the guidance offered should enable the mother to ensure for her child a greater degree of nervous stability than is often found in the product of modern nurseries. The least satisfactory chapter is that dealing with the infections of childhood; while the subject of measles, its recognition and nursing, is excellently presented, that of diphtheria is incomplete and even misleading, as, for example, the statement that "diphtheria, as everyone knows, is a severe sore-throat to begin with." Faucial diphtheria in young children is apt to be extremely insidious in its onset, the first symptoms usually being general rather than local, while in laryngeal and nasal diphtheria "sore-throat" may be entirely absent. The danger of paralysis and early cardiac involvement is not mentioned, or the necessity for prolonged rest in bed. With regard to rubella, the statement is made that infection lasts for a month, so that quarantine for this period must be maintained. Isolation for a week is all that is now usually considered necessary. In scarlet fever the desquamation is no longer regarded as a probable carrier of infection. Apart from these small points the work is admirably conceived and carried out, and should attain a well-deserved popularity.

JOURNALS.

AMERICAN REVIEW OF TUBERCULOSIS, July, 1928.—Dr. Edward N. Packard contributes an article on Massive Collapse of the Lungs. Cases of atelectasis fall into four groups: (1) those complicatory diphtheritic paralysis of the diaphragm; (2) following operations or wounds; (3) caused by obstruction to a bronchus by foreign body or tumour; (4) associated with chronic pulmonary disease, especially tuberculosis. The condition is characterised by an abrupt onset and with symptoms of acute pulmonary distress there are signs of consolidation and retraction of the affected lung. Recovery may be rapid but pneumonia supervenes in some instances. The treatment is symptomatic. Cases are described in which the condition was associated with bronchial stenosis secondary to fibroid phthisis and enlarged hilar glands.—Dr. Allen K. Krause writes on the Laboratory Diagnosis of Pulmonary Tuberculosis. After reviewing past efforts to discover a reliable test for active tuberculosis by the use of tuberculin, by examinations for opsonins, agglutinins, precipitins, and lysins, by complement-fixation tests and Arnet's blood count, he concludes that no laboratory procedure can at present carry the whole load in the positive diagnosis of tuberculosis. The results of Pirquet skin tests and of sputum examinations are of the utmost value if discrimination be used, but the fallacies attending the former are well known, and even a positive sputum test may "accompany a tuberculous condition that cannot be conceived of as active by any functional standards." Of all tests that of the sputum is, however, the most important, and repeated examinations are urged in all doubtful cases. When inoculating guinea-pigs with sputum the subcutaneous route in the groin is preferable to the intraperitoneal. It is not true that all adults react positively to tuberculin, despite the results of experiment in Vienna in 1915, which are not applicable to America in 1928. The intradermal or Pirquet test should be employed whenever tuberculosis is suspected, for a negative finding has a positive significance. Examination of the blood is also of value, for tuberculosis has comparatively small effect on the blood cells. A rapidly progressing anaemia suggests some other infection or malignant disease.—In the August number Dr. Carl R. Howson, of Los Angeles, describes the physiological anatomy of the normal thorax and the physiological mechanics of the chest as altered by artificial pneumothorax, and includes a study of the respiratory movements, and costal, respiratory, and diaphragmatic in a case of severe pulmonary tuberculosis treated by complete collapse of a lung. This lengthy article should be

read by all who are interested in collapse therapy.—The greater part of the September issue is devoted to a consideration of tuberculosis in its relation to public health.

New Inventions.

FORCEPS TO SIMPLIFY RAMMSTEDT'S OPERATION FOR CONGENITAL HYPERTROPHIC PYLORIC STENOSIS.

IN performing Rammstedt's operation undue delay and increase in shock are frequently caused by the intestine and omentum protruding from the wound. This protrusion is due to the size of the incision necessary for the fingers to grasp the pylorus and to the light anaesthesia of gas and oxygen, which is the anaesthetic of choice. To eliminate these difficulties and simplify the operation I have devised a special pair of forceps here illustrated. These forceps have

their grasping ends shaped like a pair of midwifery forceps and are lightly constructed to prevent any harm being done to the tissues. The handles are fitted with a ratchet, the first teeth of which lock before the grasping ends are in contact, the other teeth taking purchase as the forceps are closed. In this way the varying size of the hypertrophied pylorus in infants is allowed for. The forceps are made with a curve to allow the handles to lie flat on the abdomen when the pylorus is pulled up into the wound. With this instrument the peritoneum need only be incised sufficiently to admit one finger which is passed down to the pylorus. The forceps held in the other hand are then passed along the finger to the pylorus, which is grasped and pulled out through the wound. No other tissue has an opportunity to protrude. When the pyloroplasty is completed, the pylorus is allowed to drop back and the incision in the abdominal wall closed.

The forceps have been constructed for me by Messrs. Allen and Hanburys, Wigmore-street, London, W. 1.

TONSIL-HOLDING VULSELLUM FORCEPS.

HAVING had considerable difficulty with the clip of other tonsil-holding forceps, made so as to allow a guillotine or snare to be passed over them whilst holding the tonsil, I have had made a cross-action

spring vulsellum forceps which needs no clip and over which a guillotine can easily be passed while the tonsil is pulled out of its bed. In practice I have found this vulsellum to work well, provided the spring is made sufficiently strong. There being no clip to get out of order, this type is more simple in its action than the other types previously used, and is useful in both hospital and private practice.

The apparatus is made by Messrs. Allen and Hanburys, Ltd., of Wigmore-street, London.

THE LANCET.

LONDON: SATURDAY, DECEMBER 1, 1928.

THE KING'S ILLNESS.

FOR the past ten days the KING's illness has been causing very natural anxiety both at home and abroad. Though no official announcement was made until Wednesday, Nov. 21st, it is understood that he had not been in quite his usual health since the previous Saturday. Returning to town from Sandringham on Monday, he held a Council on the following morning and was able to carry out other engagements before seeking medical advice. Sir STANLEY HEVETT found him suffering from a feverish cold and called in Lord DAWSON on the next day. The KING was confined to bed but the fever persisted, and by Thursday there were signs of congestion of the right lung. At this stage Dr. L. E. H. WHITBY, of the Middlesex Hospital, attended at the Palace in order to ascertain what organisms were responsible for the infection, and on Friday radiograms of the chest were taken by Dr. GRAHAM HODGSON, of King's College Hospital. That evening a slight improvement was noted, and this was maintained on Saturday. Inflammation of the pleura was a conspicuous feature of the clinical picture, but the patient kept up his strength, and there were restful intervals, the temperature falling below the figure of 101° F. which had been recorded on Thursday night and Friday morning. A return of higher fever on Sunday inevitably resulted in sleeplessness and discomfort, and on Monday the public was warned that further spread of the pleurisy might be expected. Up to the time of going to press, however, there has been no considerable change in the physical condition, and a certain amount of rest has been secured. This is of great importance. Specific treatment is a useful aid, and may possibly turn the fortunes of the day, but it cannot put the infection to sudden rout. The last ten years have made us familiar with pulmonary inflammation whose course is inconstant, one phase developing after another. How long each phase will last is always the anxious question, and in the present case a certain amount of reassurance can be gained from the published records of temperature, which we read as indicating some curtailment of the forces of infection. At the same time it would be idle to pretend that an illness of this kind in a patient over 60 is not serious. The statements of the official bulletins have been informative though restrained, and a medical man reading them consecutively can form a picture of the illness and its course. That they may give us an increasing confidence in His MAJESTY's recovery is the earnest hope of all his subjects.

SUSCEPTIBILITY TO CANCER.

WE have been accustomed hitherto to look upon cancer as a disease which at its inception is conditioned entirely by local factors. The work of the last few years on the experimental production of cancer is in accord with this view. Thus when the skin of mice is subjected to chronic irritation by tar painting the cancer develops at the site of skin where tar painting has been applied. But as happens so often in cancer research further investigation has brought to light an entirely unexpected aspect of the problem, which tends to complicate it. The local response of the tissue subjected to chronic irritation appears to be influenced by general systemic factors which may either accelerate or delay the cancerous development. The existence of such general factors was first brought to light by Dr. J. A. MURRAY in an experimental investigation in which he subjected mice to successive courses of tarring. When a mouse is subjected to tar painting cancer will develop in a few animals after four months, in a larger number of animals round about the sixth month, some mice will develop cancer only after a much longer period of tar painting, eight, ten, or even 12 months, while in a few no cancer appears. One may say, therefore, that there are variations in the resistance, or if one prefers the converse term in the susceptibility of individual mice to carcinogenesis by tar painting. The experiment itself does not make it clear whether these differences in susceptibility reside in the skin itself or are due to general systemic factors. But at any rate it may be supposed that a mouse which has developed a cancer within six months of tar painting is a susceptible animal. One would assume, therefore, that such a susceptible animal, if subjected to a second course of tarring after the first tar cancer has been removed by operation, would again respond to this chronic irritation by the development of a second cancer within a similar period of time. But the experiment gave exactly the opposite result; these mice failed to develop cancer in response to a second course of tarring. It is not necessary that the first cancer should be a cancer of the skin or that it should have been produced by tar. Mice suffer frequently from spontaneously developed carcinoma of the mamma. Such mice are therefore susceptible to the development of cancer. If such mice, after operative removal of the growth, were subjected to a course of tarring it was again found that these mice failed to respond to this chronic irritation by the development of a tar cancer. This experimental demonstration of an inhibitory influence exerted by the development of a first malignant new growth on the subsequent development of a second neoplasm throws light on certain curious and hitherto unexplained features of cancer as it appears in man. In his Linacre Lecture on Multiple New Growths,¹ Dr. MURRAY pointed out that the extraordinary rarity of multiple malignant new growths of different organs or tissues could be accounted for in this way. An even more interesting application is given by him in the annual report of the Imperial Cancer Research Fund² which has been issued this week.

In this country and in a number of other countries in which trustworthy cancer statistics are available—Dr. MURRAY has chosen England, Holland, Switzerland, and Japan—the total incidence of cancer is about the same for the male and for the female sex. Now in this country approximately 30 per cent. of

¹ THE LANCET, 1927, II, 800.
² Twenty-sixth Annual Report of the Imperial Cancer Research Fund, 1927-28. Offices of the Fund: 8-11, Queen-square, London, W.C.

the total mortality of cancer among women is due to cancer of the breast and uterus—i.e., organs peculiar to the female sex—while the organs peculiar to the male sex show a very low incidence of cancer. One would expect, therefore, to find that the total incidence of cancer in men is considerably lower than that of women. But, as already stated, it is approximately the same, because in men the organs common to both sexes are more frequently affected by cancer than in women, and this greater frequency is of such a degree that it equalises the frequency with which the breast and uterus are the seat of cancer in women. The same relationship is found to exist when the incidence of cancer in men and women for each of the other three countries mentioned is examined. The same phenomenon appears again when a comparison is made between the incidence of cancer among women of the four different countries. In this country, as we have seen, cancer of the breast and uterus represents about 30 per cent. of the total incidence of cancer in women. The frequency with which breast and uterus are affected is about the same. In Holland both cancer of the breast and cancer of the uterus are only half as frequent as in England. Switzerland takes an intermediate position. In Japan cancer of the breast is a rare disease. Here again we would expect a corresponding difference in the total incidence of cancer among women of these four countries, and again we find that the total incidence is approximately the same. Dutch women suffer more frequently from cancer of the digestive tract than English women, while Japanese women suffer more frequently from cancer of the uterus. The higher incidence of cancer in one organ—or group of organs—so nearly balances the lower incidence in another group that the total incidence among the women of the four different countries is almost the same. In Dr. MURRAY's report these remarkable statistical relationships are represented very clearly in a diagram which those interested in the subject are advised to study. Instead of regarding the development of cancer in any particular organ as an independent phenomenon, unrelated to the development of cancer in other organs, and instead of looking upon the total incidence of cancer as merely the sum total of all these unrelated processes, this diagram now presents us with an entirely different picture. It would now appear as if the total incidence of cancer were determined by the susceptibility to cancer and that within that compass the different organs are affected by cancer either according to their special organ susceptibility or according to the extent of the various carcinogenic factors of chronic irritation which are allowed to act upon them.

This difference in outlook can best be illustrated by an example. The higher frequency of cancer of the digestive tract in men has been attributed to the more strenuous lives that men are supposed to lead so that they are supposed, for instance, to eat their food hurriedly, and partly to their habits of smoking and drinking. The explanation is obviously made ad hoc and has never been very convincing. It is, moreover, no longer true to-day, when a large number of women have exchanged the alleged leisure of keeping house for a business career and when smoking and drinking have ceased to be a privilege—or vice—reserved for the male sex. According to the susceptibility theory women suffer less frequently from cancer of the digestive tract, because among women susceptible to cancer a large number develop cancer of the breast and uterus and pro tanto diminish the number of those who could develop cancer of the digestive tract. Another illustration is afforded by a recent

investigation into the incidence of cancer of the breast in Holland and in this country. As already stated, cancer of the breast and uterus is almost twice as frequent among English women as it is among Dutch women. A committee of distinguished statisticians and pathologists appointed by the Health Committee of the League of Nations has carried out an exhaustive investigation into the various possible factors which might conceivably be responsible for this difference, but nothing could be found to account for it. The investigation was so careful and comprehensive that this negative result can be accepted as a positive contribution to our knowledge; it makes it unlikely that there are any external factors which render Dutch women relatively immune to cancer of the breast and uterus. But since in Holland both sexes suffer more frequently from cancer of the digestive tract than the corresponding sexes in England, it seems probable that the habits and conditions of life in Holland predispose to this latter form of cancer and since of the susceptible women in Holland more are affected by cancer of the digestive tract, a correspondingly smaller number is left over in which the breast and uterus may develop cancer. At first sight such a conception would appear to offer a very dark outlook introducing the cold-blooded conception of "effectual calling" of Scottish theology into the realms of pathology. Supposing it were possible by local methods to diminish the incidence of cancer in any particular organ, say, cancer of the uterus, then, if this view held good, there would be a corresponding increase in cancer of some other organ. But, as Dr. W. CRAMER has pointed out in two recent papers,³ there is a brighter side to it. If there is such a thing as susceptibility it must depend on general systemic factors which can be investigated experimentally and which may be capable of being influenced. Already it has been shown that susceptibility is not a fixed condition, but that it can be raised and lowered. It is a new way of looking at the cancer problem and, if further progress along these lines is made, it may be possible to increase the resistance to the development of cancer.

THE MEDICAL PROFESSION'S PART IN LEGISLATION.

WHEN a Member of Parliament is chosen to be president of the Epidemiological Section of the Royal Society of Medicine, it is appropriate that his presidential address should examine the processes by which the ideas of the medical profession can obtain legislative effect. There are 13 medical Members of the House of Commons; what can they do to initiate and mould new laws? In answering this question Lieut.-Colonel FREMANTLE's presidential address does not overrate the powers of any private Member of Parliament. The private Member can help to form public opinion outside as well as inside the House. By legitimate propaganda at question-time he may focus attention upon some needed reform. By sedulous work in committee or by using some scanty opportunity in debate, he may have the chance to indicate an amendment or to interpolate a new clause. He may even draft a whole Bill which will be officially printed and may thus arouse public notice. With the luck of the ballot he may actually find himself expounding his own proposals on some Friday evening. The Government's time-table for

³ Systemic Factors in the Genesis of Cancer, Brit. Jour. Exp. Path., 1926, vii., 1; Ergebnisse und Ziele der Krebsforschung, Zeitschr. f. Krebsforschung, 1928, xxvi., 194.

the session may block the private Member's chances; but, on the other hand, the Ministry of Health may be glad to see some topic unofficially brought forward; many a useful measure may begin its life as a private Member's Bill, and, on subsequent adoption by the Government, may receive the added facilities which the appropriate Department's blessing will confer. Examples of such Bills in recent years have been those dealing with births and deaths registration, maternity and nursing homes, and mental deficiency. Yet nowhere, either among Government proposals or private Members' Bills, do we find measures for the embodying of the Lunacy Report recommendations or for giving effect to the Voluntary Hospitals Committee Report, or the more recent Report of the Vaccination Committee. Here are medical subjects which our medical Members seem powerless to push forward. They speak in Parliament with the confidence of acknowledged experts; their speeches are published abroad; their interest in health matters is conspicuous; yet somehow the necessary impetus from outside the House is lacking. How is public support to be mobilised? How is the authoritative voice of the whole medical profession to be heard? Even the small band of medical Members can hardly be drilled to team-work. They represent their constituencies, not their profession. They were sharply divided, for instance, over the compulsory notification proposals in the Edinburgh Corporation Bill last session. And, as they enter Parliament as members of a political party, we cannot be surprised if their divisions follow the lines of party politics. For better or for worse the country is wedded to the party system; the Whips expect obedience; the machine of ministerial legislation cannot be operated unless definite calculations can be made of support and opposition. Left to a free vote—as in the debate upon the Prayer Book—the running of the machine is incalculable.

Seen historically (and Dr. FREMANTLE rightly insists on the value of history in the study of public health), our national tendency in legislation is to proceed from the particular to the general. English criminal law is full of statutes which have followed some specific incident or decision in the police-court or at assizes. Similarly, in the domain of health legislation, a famine or a cholera epidemic has more readily stimulated our law-makers than any abstract study of theoretic reforms. Being a practical people, we legislate *ad hoc*. Perhaps it is the misfortune of medical ideas that they seem too much the affair of experts. Yet Parliament will give the experts a free hand upon occasion. How many Members of Parliament perused the immense Bills which reformed conveyancing and the law of property in 1925? How many understood what they read? Our preference for concrete piecemeal legislation happens to have its happiest illustration in the field of public health, where Parliament has so often allowed the trying out of an experiment locally and subsequently has applied the new law to other areas or to the whole country if the experiment has proved successful. We like to follow legislative precedents; we prefer the empiric method to philosophic theory. Moreover, the policy of proceeding area by area is in harmony with our traditions of local self-government. It is the sensible principle that those who feel the pinch of the shoe shall themselves correct what is amiss. If we want to have a healthy nation we must work for sound local government. Central guidance, help, and stimulus are necessary, but it is the local impetus which will make the progress. If our medical Members of Parliament can be satisfied that the new Local Government Bill conforms to this

principle and aims at sound local government rather than a colossal bureaucracy, they may find themselves able to support it with enthusiasm and with concerted counsel as the representatives both of their constituencies and their profession.

Annotations.

"Ne quid nimis."

VOLUNTARY HOSPITALS AND MOTOR ACCIDENTS

THE report¹ on voluntary hospitals, which has just been issued by Mr. R. H. P. Orde, director of the Central Bureau of Hospital Information, is practically complete, for it envisages over 99 per cent. of the total voluntary hospital bed accommodation of Great Britain (exclusive of London). The actual number of hospitals reviewed is 755, of which 75 per cent. show credit balances, giving welcome evidence of recovery from the previous bad year. In spite of adverse trade conditions, the total of workmen's contributions reached the highest figure yet attained. One of the features in this valuable report is a symposium on the difficulties experienced by hospitals throughout the country in dealing with road accident cases. It is common knowledge that during the past few years these accidents have greatly increased and many hospitals, especially those on the main lines of traffic, have with difficulty been able to provide beds and treatment for the injured, whether motorist or pedestrian, without encroaching on accommodation already too limited for the locality in which they are situated. The report summarises 98 replies, received from 160 provincial hospitals, to letters asking for information regarding the volume of work and the cost involved in treating such cases. From these replies it is deduced that the hospitals treated during the year 1927 approximately 26,000 in-patients and 39,000 out-patients as a result of motor accidents, at a total cost of £230,000, the amount received by the hospitals from insurance and from the patients themselves towards their cost being only some £26,000. The records, although incomplete, justify a belief that these figures are a reasonable approximation to the truth. Only one of the hospitals sending in returns has received as much as one-half of the cost incurred; 10 have received nothing at all; probably 11 per cent. represents fairly the amount which the majority of the hospitals recover by gift or payment. A factor in the problem is the unevenness with which the burden falls on different hospitals. Two hospitals on the outskirts of London, with 112 and 52 beds respectively, treated 164 and 100 in-patients, while a Midland hospital and a north country hospital of 124 and 140 beds treated only 62 and 36 in-patients. None of the steps taken appears to have adequately met the situation. In one hospital patients are interviewed and a written undertaking obtained to include hospital costs in any claim made. In another patients are asked whether they are making claims for compensation, and sums varying from £5 to £70 have been received. In a third each patient, on discharge, has been given a bill for the full cost of maintenance, with a view to his passing it on to the person who caused the accident. An obvious difficulty is due to the large proportion of patients who do not belong to the district in which the hospital is situated; in a small hospital with a limited area the proportion may be as high as 33 per cent., while in a city hospital serving an extensive county area it may be as low as 3 per cent. Many people think that the solution of the

¹ The Voluntary Hospitals in Great Britain, excluding London. Ninth Annual Report for the Year 1927. Published by the Central Bureau of Hospital Information under the auspices of the British Hospitals Association and the Joint Council of the Order of St. John and the British Red Cross Society, 19, Berkeley-street, London, W. Pp. 125. 1s.

problem is to be found in the compulsory insurance of motorists, but Sir Arthur Stanley, in his presidential foreword, remarks that this method has been carefully examined and does not appear to be practicable, if only for the reason that many of the persons involved in road accidents are not themselves motorists. Sir Arthur expresses his personal hope that motorists themselves will come to the rescue by establishing some central voluntary fund from which the hospitals could be helped. Articles contributed by Lord Montagu of Beaulieu and Sir William Goschen also point out the difficulties in solving the problem by insurance alone. While nothing should be done to alienate the practical sympathy of the voluntary giver, it is clear from the views expressed in reply to the questionnaire that some extension of voluntary hospital support is necessary in order to enable hospitals to meet the cost of treating patients suffering from road accidents.

NUTRITIONAL ANÆMIA IN INFANCY.

AN investigation extending over the last three years and comprising nearly 800 cases with 3000 hæmoglobin estimations has been made by Dr. Helen Mackay, assisted by Miss Lorel Goodfellow, and has revealed the prevalence of anæmia among London infants. Discussing her results at the Section for the Study of Disease in Children of the Royal Society of Medicine on Nov. 23rd, Dr. Mackay said that the anæmia was largely nutritional in origin and was due to a deficiency of iron, possibly associated with other factors. It is known that an infant obtains its iron needs not only from milk, which is poor in iron, but also from a store in the liver, and it seems likely that this store may be unduly low in many London infants. The hæmoglobin level of new-born infants has been shown by many observers to be over 110 per cent. at least. The average hæmoglobin percentage in the blood of fairly healthy artificially fed London infants shows, according to Dr. Mackay, a sharp fall from this high level to about 65 at the age of 2-3 months, a rise to about 70 at 5-6 months, and then a steady fall, reaching about 65 when the child is a year old. The continuous administration of iron, starting when the infant was less than 2 months old, raised the average hæmoglobin percentage to about 80 by 4 months old and onwards. Twins, premature infants, and other infants whose birth weight is under 6 lb. are specially in need of iron treatment. The selection of the iron salt is of importance; iron and ammonium citrate proved effective. The salt used contains a trace of copper, but it is not known whether this had any influence on the results produced. The iron was satisfactorily administered on a large scale by incorporating it in a dried milk.¹ No evidence was obtained that want of light is an ætiological factor in anæmia in infancy, and artificial light therapy did not cure it. No vitamin deficiency appeared to be involved. The value of liver treatment is still under investigation, but the results so far obtained can be explained on the assumption that liver treatment is efficacious only because it provides a source of iron. The routine administration of an iron salt to artificially fed infants is advocated by Dr. Mackay on the ground that, by preventing the anæmia from which most of them would otherwise suffer, it would raise the level of health of our infant population.

THE CLASSIFICATION OF PNEUMONIA IN CHILDREN.

THE differential diagnosis of the various types of pneumonia encountered in early life is admitted by experts to be a matter of some difficulty, not only because mild cases exhibit very few physical signs but also because lobular types ending in crisis and rapid recovery are very difficult to classify, even when physical signs are well marked. When it is agreed

that the prognosis of the various types of pneumonia differs considerably it is clear that exact diagnosis is a matter of great importance, but examination of statistics derived from large numbers of cases shows that the personal factor amongst clinicians must give rise to serious difficulties in the diagnosis of these diseases. Thus Heiman, reporting on 215 cases, found the relation of lobar to broncho-pneumonic cases to be 1-17, whereas Pisek and Pease in 550 cases found the relation to be 1-2, and Morse in 178 cases gives it as 2-1. All these figures were derived from children during the first two years of life. When the statistics are taken from somewhat older cases we find series such as those of Heiman of 336 cases below the age of 6 in whom the relation of lobar to broncho-pneumonia was 1-6, and Holt dealing with 370 cases up to the age of 4 gives the relation as 1.0-0.4. It would seem clear from these figures either that the variety of pneumonia in children changes with locality, or that diagnostic inaccuracy is much more prevalent than is desirable. The latter explanation is suggested in a paper² by Dr. J. P. Crozer Griffith, of Philadelphia, who has made a combined study of the clinical, radiological, and post-mortem findings in 26 fatal cases under his care. Particular attention was paid to securing the highest possible degree of accuracy in diagnosis in these cases, and the post-mortem diagnosis may be accepted as correct. There can, indeed, be no other final criterion. Unhappily for the peace of mind of both clinician and radiologist there were only six cases in the 26 in whom clinical and X ray study both yielded accurate diagnosis. In ten cases only were the clinical and X ray diagnoses in agreement, and of these ten the diagnosis was wrong in four cases. Examining the matter from a different angle, the clinical diagnosis was correct in 15 of the 26 cases and X ray diagnosis correct in only 12, but it must not be supposed from this that the X ray diagnosis was without value because six cases were accurately diagnosed by this method which had been wrongly classified by the clinician. In discussing this paper Dr. Griffith emphasises the fact that in addition to the two main groups of broncho- and lobar pneumonia all clinicians recognise certain subtypes, but until more precision can be obtained as to which of the two main groups a case should be placed in, it seems unwise to make any attempt at finer diagnosis.

THORACOPLASTY IN PHTHISIS.

THE late results of thoracoplastic operations are the subject of a paper² by Dr. Morten H. Gjessing, assistant to Dr. O. Tandberg, of the communal hospital in Lillehammer. Their material consists of 103 cases of pulmonary tuberculosis treated by extrapleural thoracoplasty between August 13th, 1920, and Feb. 15th, 1928. The first 26 operations were performed under local and the remainder under general anaesthesia. In every case a pneumothorax had been attempted or put out of court because the X ray picture had indicated such extensive adhesions that this treatment seemed unfeasible. In eight cases the thoracoplasty supplemented an already existing partial pneumothorax. The operation mortality was 8.7 per cent., nine patients having died immediately or soon after the operation. Seven other patients died in the course of the following year. A classification of the operation deaths according to sex and the side operated on brought out the facts already demonstrated by Sauerbruch and others that the mortality is much higher in men than in women and for operations on the right side than for those on the left. Thus, there were seven operation deaths out of 45 right-sided cases, whereas there were only two operation deaths among the 58 cases in which the left side was operated on. Again, there were seven operation deaths among the 45 male patients, whereas there were only two such deaths among the

¹ This was supplied by the "Cow and Gate" firm, who have now placed it on the market under the name of Hæmolac.

² Jour. Amer. Med. Assoc., 1928, xci., 1331.
² Norsk Magazin for Lægevidenskaben, September and October, 1928.

58 female patients. It would seem that this combination—male patient with operation on the right side—entails the remarkably high operation mortality of about 25 per cent. After discussing the anatomical and physiological differences in the two sexes which may account for this curious phenomenon, Dr. Gjessing gives the following analysis of the late results of thoracoplasty. Of 88 patients observed for from one to seven and a half years after the operation, 36, or 40.9 per cent., were fit for work, 14 were partially fit for work, 6 were better but not fit for work, 4 showed transitory improvement, 2 showed no change, and 26, or 29.5 per cent., were dead. As might be expected, the mortality in this class of case is highest during the first three years after the operation, and of the 52 patients with an observation period of three to seven and a half years since the operation 20 were fit for work, 6 were partially fit for work, 3 were unfit for work but better, 1 showed temporary improvement, and 22 were dead. In other words, more than 50 per cent. of the patients selected for this operation derived lasting benefit from it. Dr. Gjessing finds it useful to put the phrenic nerve out of action, and concludes with an appreciative discussion of exsaisis as a measure supplementary to thoracoplasty.

AVERTIN ANÆSTHESIA.

AVERTIN has now been used for rectal anæsthesia over 100,000 times in Germany, but its "advantages are not yet finally determined on a basis of security" according to Prof. V. Anschütz who contributes a valuable article¹ on the subject. Regulation of the dosage is, of course, the great obstacle to invariable success with this as with other anæsthetics administered per rectum. The usual method of putting in the entire estimated dose within a few minutes has given at Kiel success in 80 per cent. of the cases. The alternative procedure of feeling the way, so to speak, and giving the injection by fractional administration requires so much time and patience that it does not appear to be a practical proposition. Prof. Anschütz forbids any enema on the morning of operation so as to avoid risk of irritating the rectal mucosa and of leaving water behind, which would, of course, upset the proper strength of the injected avertin solution. He uses an airway, leaving it in position till the patient awakes, sometimes for hours at a stretch. Prof. Anschütz regards avertin anæsthesia as the method of choice in elderly patients and in the presence of pulmonary, aortic, or renal complications—"in a word, in all cases where ether anæsthesia is contra-indicated."

HOSPITAL BEDS IN THE SHEFFIELD AREA.

IN our issue of Oct. 27th appeared a short paragraph entitled *Overcrowding at Sheffield Infirmary*, which suggested so serious a shortage of hospital accommodation in Sheffield, that beds had to be made up on the floor, and that there was a long waiting list of medical and surgical cases. The information, received from a trusted correspondent, which was embodied in this paragraph, did not seem to us improbable, since the fact of shortage of beds and overcrowding is only too true of some other hospitals in the area, and was the occasion of the recent decision in favour of a system of coöperation and coördination between the hospital authorities of the district, with Sheffield as the pivot of the scheme. But we have been informed, and have already taken occasion to declare, that the information did not refer to the Royal Infirmary, Sheffield (or indeed to any other hospital in that town), and we sincerely regret any trouble or annoyance which it may have given to the hospital authorities there. The area of shortage of accommodation, which has a radius of some 25 miles, includes Barnsley, Mexborough, Doncaster, Denaby, Rotherham, Worksop, Retford, Bakewell,

and Chesterfield. The scheme includes four Sheffield hospitals with a total of 1067 beds and eight hospitals outside with about 700 beds, the autonomy of which will be in no way affected. A regional conference a few months ago reported that in the Sheffield area there were more than 2000 and in the outside districts another 1000 patients needing hospital treatment but unable to be accommodated. At the same time the poor-law institutions had vacant beds in the areas of Sheffield, Doncaster, and Worksop. The attribution to Sheffield of the hospital shortage which exists elsewhere is the more regrettable inasmuch as Sheffield has made great efforts to supplement its accommodation for the sick, the number of beds in the local hospitals having increased by 320 during the last eight years. This excellent increase has been facilitated by the success of the penny-in-the-pound scheme which last year brought in a sum of more than £110,000. In Doncaster the rapid increase of the industrial population, owing to the development of coal-mines in the immediate vicinity, has outgrown the hospital accommodation. Traffic emergencies claim more and more of the beds allocated to accidents in the collieries and other industries. In the last six years the number of beds at the Royal Infirmary has advanced from 65 to 121 and every temporary measure has been taken to meet the shortage. The daily average number of beds occupied was in fact 117.5 for the year ended Sept. 30th. Last May work was commenced on the first block of a new infirmary which will be ready for occupation in the autumn of 1929; this will provide 150 beds at a cost, including the new nursing staff accommodation, of £70,000. The industrial situation has led to difficulties in the project, but colliery owners, glassworks, and other firms have offered timely help. A complete new hospital of 300 beds at a cost of £300,000 is the ultimate objective.

ENUMERATION OF NEMATODE EGGS.

AN instance of inter-reaction between medical and veterinary practice is seen in H. O. Monnig's² attempts to apply to sheep's faeces certain counting methods which have been used for enumerating nematode eggs in human faeces. He originally employed a technique in which straining through a series of sieves followed by sedimentation for ten minutes had given inexact results. Since straining through a single sieve has been found in a particular series of experiments to remove on the average not less than 60 per cent. of human hookworm eggs, and since the further loss of eggs which will occur on decantation after sedimentation by gravity for ten minutes is unknown, these irregularities are easy to understand. When this method failed he tried the Hamburg coverslip counting technique, as employed on dog's faeces by Hung³ in Fülleborn's laboratory. This is a gravity floatation method which samples a known fraction of the surface of the vessel in which floatation is effected. It was checked by Hung against Stoll's technique and against one which was Lane's direct centrifugal floatation (D.C.F.) in name and in principle, but in none of the details essential for success. Monnig found the Hamburg method to fail, when applied to sheep's faeces, by reason of the amount of floating grass which obscured vision. This confirms a finding, not generally known, that when Fülleborn used the method upon human material for egg-counting in an Argentine hookworm campaign, he found he could not rely upon it. Monnig did not use D.C.F. pushed to finality since he believed that here, too, the amount of float would prevent accurate counting. He turned instead to Stoll's caustic soda solution technique, but found that it was not to be depended upon for counting eggs in sheep's faeces. He very rightly points out his good reasons for refusing to accept the statement of advocates of this technique that irregular counts mean inaccurate counting, that the fault is in the man and not in the

¹ *Zentralblatt f. Chirurgie*, October, 1928.

² *Amer. Jour. Hyg.*, November, 1928.

³ *Arch. f. Schiff- u. Tropen-Hyg.*, 1926, xxx., 399.

method. He then indicates certain modifications which he has made in it, and he believes, as the result of eight counts only, that he has rendered it reliable. In all the circumstances, confirmation on a considerably larger scale is likely to be expected before this conclusion is generally accepted. In this instance inter-reaction between medical and veterinary practice has not yet proved particularly fruitful, the methods used not having an entirely sound foundation. But where conditions are more strictly comparable, there may at any time recur such remarkable results as have just been obtained by Hindle, whose knowledge of the work of Laidlaw in dog distemper and of Charles Todd on fowl plague led him so directly to the preparation against yellow fever of the vaccine whose potentialities for good are of such a promising nature.

DR. OLIVER GOLDSMITH.

THIS week sees the bicentenary of the birth of Oliver Goldsmith. He was born on Nov. 29th, 1728, the second son of the Rev. Charles Goldsmith, whose character is portrayed by his son in his description of the preacher in the "Deserted Village." "A man he was to all the country dear, and passing rich with forty pounds a year." *Res angusta domi* was such that it was proposed that Oliver should qualify himself for a trade, and with this end in view he was sent to the village schoolmaster to be instructed in the three R's. This worthy also figures in the "Deserted Village." To the importunity of Oliver's mother is due the fact that his father made some effort later on to give the boy a decent education in order to qualify him for one of the liberal professions. He was sent to the school at Athlone and at the age of 15 went to Dublin, where in June, 1744, he was admitted sizar at Trinity College. He ran away to Cork, after being chastised by his tutor, but thinking better of it he returned and took his B.A. in 1749. After many vicissitudes he went to Edinburgh in 1752 to study medicine and later to Leiden. Returning to England in a penniless condition, he accepted the post of usher in an academy at Peckham; this proving uncongenial, he became assistant to a chemist in the city, and after working in his laboratory for some time he at last began practice in Southwark and later moved to the Temple. In 1761 he made the acquaintance of Dr. Johnson and became a member of the Literary Club. He died, heavily in debt, in his forty-fifth year in 1774. His death was accelerated by taking a James's powder, which he insisted on doing despite the advice of his apothecary and physician who told him not to do so. Whatever his shortcomings in physic and his financial difficulties may have been, "Poor Goldie" certainly contributed some imperishable works to English literature, while the elegy on the death of a mad dog, with Caldecott's pictures, is among the childhood recollections of most of us. Horace Walpole called him "an inspired idiot," and Garrick protested that "he wrote like an angel and talked like poor Poll," but we can all of us now subscribe to surly Sam's sentiments as recorded in his epitaph in Westminster Abbey, "*nihil quod tetigit non ornavit*." Goldsmith's memory is among the chief glories of the medical profession.

A SIMPLE INDEX OF ANÆMIA.

THE colour of the face is admittedly a poor guide to the presence or absence of anæmia; the colour of the conjunctiva, as observed in the lower lid, may serve somewhat better, but the information it affords can hardly be described as accurate. Estimation of hæmoglobin and a count of the red cells carry us further, but it is necessary to bear in mind that without a knowledge of the volume of the circulating blood even these modern methods may give information wide of the mark. So far as the oxygen-carrying function of the blood is concerned, the important factor is the amount of hæmoglobin available per unit of body tissue; whether the hæmoglobin be con-

centrated or diluted does not, within limits, greatly matter. Dr. W. W. Duke, of Kansas City, has drawn attention¹ to what would appear to be a valuable clinical test for the determination of the presence or absence of anæmia, depending upon the observation of the colour of the palms of the hands. The fact that the colour of the palms when held in the same position is much the same in all healthy persons seems to have escaped the clinician. It is, of course, well recognised that the vessels of the palms are not subject to the same variations in calibre as those of the face; it is equally well known that even in dark-skinned persons the palms are relatively free from pigment. There are, it may be, limits to the truth of this statement, but the fact remains that the palms of most individuals of European extraction show little pigmentation. This being the case, it is obvious that they offer an admirable field for the observation of the concentration of hæmoglobin in the circulation, at least in those who do not habitually do manual work. For control a standard palm is necessary; this should be the palm of the observer, if he has first made sure that his palm colour is that of the healthy young adult. For the actual observation it is essential for observer and observed to be in the same posture and for the palms of both to be held at the same level. The difference in palm colour brought about by variation of level in respect to the heart can be demonstrated by anyone who will hold one hand above the head and allow the other to hang for a minute and then rapidly compare the two. Using this method, Dr. Duke states that he is readily able to identify even comparatively slight degrees of anæmia and plethora, while it serves as a ready means of following the degree of hæmoglobin restoration in the course of infusion of blood. This is the sort of observation that might have been expected of Hippocrates; it is refreshing to find such a simple and yet scientifically sound method turning up nowadays.

THE LIVER IN PRIMITIVE MEDICINE.

THE great and sudden popularity of liver treatment prompts inquiry into the part it has played in medicine in the past. According to the Babylonians, says Dr. H. Vorwahl,² the liver was the central organ and liver inspection was the chief form of augury. In man it was considered the source of the blood, and after the psycho-physical parallelism of the times, as the seat of the affections. This belief descended to the followers of Mithras, who recognised a triple fire-goddess corresponding to the three parts of the soul, and located the passions in the liver; it is also reflected in the Old Testament.³ Horace wrote of it as the seat of love in words with a somewhat startling significance to clinical ears—"non ancilla tuum jecur ulceret ulla"—and Juvenal spoke of the liver of an angry man as burning with fury. The Galenic conception of its function, which prevailed for many centuries, was that it converted chyle into blood. Megenberg, a leading anatomist of the fourteenth century, stated that it separated the valuable components of the chyle from the waste and transmitted them to the limbs as blood. This, however, is somewhat sophisticated lore, and in many regions where science has not penetrated the old Babylonian beliefs survive. Sir James Frazer says of the natives of Darfur, in the Western Sudan, that they eat the liver of animals to increase their health, and consequently the health of their souls. The custom is universal among the Arabs and other Sudanese tribes of taking every opportunity to eat raw liver, which is supposed to confer virility. Women, Frazer remarks, are forbidden to eat liver, as they have no souls. South-West African tribes excise the liver of a brave enemy and burn it to ashes, which are employed in the circumcision ceremonies to confer courage upon their young men. Our phrase, "white-livered coward,"

¹ Arch. Int. Med., 1928, xlii., 533.

² Deut. Med. Woch., 1928, xlii., 1769.

³ Lamentations, II., 11.

conveys the same idea. Somewhat strange, however, is the phrase "white-livered" applied to women of strong sexual instincts in German peasant vernacular. The therapeutic use of liver is also general among primitive peoples; the Turks use liver applications in the treatment of the eyes after the manner related in Tobias, and we must admit that its use in pernicious anæmia is still just as empirical. On April 28th of this year we gave a few doubtful instances of its popular employment for anæmia, and mentioned that Nägeli records improvement in a patient who ate a great deal of *Blutcurst*. Black pudding is given for anæmia in some parts of England, whilst a letter in our correspondence columns on March 31st relates the use by Chinese doctors of the powdered liver of a carnivorous crow.

It is announced that the University of Edinburgh is to receive £15,000 for the endowment of the department of surgery. The sum of £10,000 has been given by the Rockefeller Foundation and the remainder by Mr. Thomas Cowan, whose contribution will form a surgical research fund.

WE regret to announce the death after a brief illness of Mr. Charles Walter Good, who was for more than 20 years the manager of THE LANCET. A Londoner by birth, he entered the printing trade at an early age and founded in Burleigh-street, Strand, a business which became the Church Printing Company. So when he was invited by Mr. Wakley to help him in the production of this journal he already possessed an experience as a practical printer which made his work of the utmost value. On his retirement in 1920, the proprietors marked their appreciation of his services by the gift of a motor-car. He then went to live at Exhall, Warwickshire—where his son-in-law, the Rev. Frank Melville, was vicar—and devoted his spare time to church work, later removing to Pinhoe, Devon, where he qualified as a lay reader for the diocese of Exeter, and was shortly to have been ordained. Mr. Good was in his sixty-eighth year and leaves a widow and two daughters.

ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.—An appeal is being made for £60,000 to clear off the debt upon this institution. Since 1918 the number of beds has grown from 200 to 420, the number of in-patients from 1161 to 2500, and the out-patients attendances from 48,700 to over 80,000. There are still more than 800 children awaiting admission.

PRESENTATIONS TO MEDICAL MEN.—Dr. John Osbert Wilson, joint parish medical officer of Huntley, who has retired after 50 years practice in his native town, was on Nov. 16th entertained at dinner in Stewart's Hall and presented with a gold wristlet watch, suitably inscribed, as a token of the great esteem in which he was held by the community. Mrs. Wilson was also presented with a platinum and diamond wristlet watch.—Presentations by the townspeople of Kirkby Lonsdale and farm tenants were made on Nov. 19th to Dr. William Smith Paget-Tomlinson in recognition of his public work and in celebration of his eightieth birthday. Dr. Paget-Tomlinson retired from practice over 20 years ago, and was High Sheriff of Westmorland in 1897. He established the Westmorland Sanatorium for Consumptives, and since going to Kirkby Lonsdale from Forton nearly 40 years ago has been a munificent benefactor of the Grammar School, the Church, and the School for Clergy's Daughters at Casterton.

DONATIONS AND BEQUESTS.—The late Captain Bernard John Merlin Walsh, of Nayland, Suffolk, left £1000 each to the Hospital and Home for Incurable Children, North Court, Hampstead, the Hospital for Sick Children, Great Ormond-street, the Paddington Green Children's Hospital, St. George's Hospital, Hyde Park-corner, and the Essex County Hospital, Colchester.—By will the late Mr. Herbert Pickersgill, of St. Paul's-road, Manningham, Bradford, left £10,000 to the Dewsbury and District Infirmary, provided it is still supported by voluntary subscriptions and not controlled by the State or the local authority.—Mrs. Eliza Annie Smith, Sheffield, left £500 each to the Royal Hospital, the Royal Infirmary and the Jessop Hospital, Sheffield.—Miss Lily May Broderip, Durnham Park, Bristol, left £1000 to St. Luke's Hostel, Fitzroy-square, for founding two beds in memory of her mother and sister Eva.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XIII.—TESTS OF RENAL EFFICIENCY.

BY G. A. HARRISON, M.D.,
CHEMICAL PATHOLOGIST TO ST. BARTHOLOMEW'S HOSPITAL.

II.*

BLOOD ANALYSIS: DYE TESTS.

BLOOD ANALYSIS.

THE normal findings in a blood analysis are as follows:—

Substance.	Mg. per 100 c.cm.	B.P. or S.†
Urea { On average diet 2½ hr. after 15 g. urea	15 to 40 (even 50 in old age)	B.P.S.
Non-protein nitrogen	25 to 50	B.
Uric acid	1 to 4	B.P.S.
Creatinine	0.7 to 2	B.P.S.
Cholesterol	100 to 200	B.P.S.
Proteins { Albumin	3400 to 6700	P.S.
{ Globulin	1200 to 2900	
Inorganic { Adults	2 to 4	P.S.
{ Children	4 to 6	
Calcium	9 to 11	S.
Alkali reserve (Plasma bicarbonate)	50 to 75 vols. CO ₂ per cent.	P. (citrated).

† B. indicates whole blood (oxalated), P. plasma (oxalated except in case of calcium), and S. serum.

In practice, an estimation of either urea or non-protein nitrogen is all that is necessary in the majority of cases. Urea is generally estimated rather than non-protein nitrogen because the technique is simpler. Since urea nitrogen constitutes by far the greatest percentage of the total non-protein nitrogen, it is only rarely that the latter test gives more information than the former.

BLOOD-UREA.

In this test the concentration of urea in the blood is determined to see whether there is a retention of urea.

Technique.

The vast majority of methods require at least 1 c.cm. of blood; 3 c.cm. is desirable as a rule. Therefore the blood is obtained by venepuncture. H. E. Archer and others, however, have modified Folin's technique, so that estimations may be made on 0.2 c.cm. blood obtained by skin puncture. This micro-method is valuable if little blood is available, and particularly in children, or when repeated determinations have to be made on the same patient (blood-urea curves). It does not matter whether whole blood, oxalated plasma, or serum be used, in that urea is approximately evenly distributed between corpuscles and plasma. The urea content of the blood and of the various body fluids are practically uniform. This point is of practical importance in that cerebro-spinal fluid or œdema fluid may already have been obtained and be available for analysis. It has even been suggested that the saliva be utilised for estimation of urea instead of the blood, but recent work casts doubt on the value of the salivary urea. In nearly all methods urea is estimated with the aid of urease. The hypobromite method is not recommended for blood, though it will readily reveal gross retention of urea.

Interpretation of Results.

The concentration of urea in the blood is very little influenced by ordinary mixed meals. It does not matter, therefore, at what time of the day the blood

* Part I. appeared in THE LANCET last week.

is obtained. The blood-urea, however, though slowly, is sometimes extensively affected by great reduction of protein in the diet. For this reason the blood urea may be misleading in some cases of kidney disease. Cases of uræmia have been reported in whom the blood-urea was reduced from very high values to within normal limits solely as a result of the restriction of proteins. The same difficulty is occasionally experienced in cases of enlarged prostate with severe anorexia. For this reason the estimation of urea at a known interval after a standard dose of urea has been advocated. A convenient method is to combine the urea-concentration test with the estimation of urea in the blood. Urea administered by the mouth is rapidly absorbed. At the end of an hour, after 15 g., the blood-urea is approximately doubled in a normal person.

The chief difficulty in interpreting the meaning of an increase in the urea content of the blood lies in the exclusion of non-renal causes of increase. Thus severe diarrhoea, gastro-enteritis, &c., and, in fact, any cause of severe anhydramia, tends to raise the blood-urea. A failing circulation has a similar effect, in this case, owing to the diminution of urinary secretion as a result of the fall in blood pressure. In addition to cardiac cases proper, the circulation is deficient in the terminal stages of many diseases. For this reason the value of estimations of blood-urea made shortly before death is often difficult to assess. Another cause of slightly raised values is excessive protein destruction—e.g., in diabetics submitted to severe undernutrition. The rise of blood-urea in these non-renal cases is usually only moderate, of the order of 50 to 100 mg. per 100 c.cm. of blood. As MacLean has emphasised, they may often be distinguished by estimating the concentration of urea in the urine, which will be found to be high, over 2 per cent. and sometimes over 4 per cent. A fuller account of the interpretation of blood-urea analyses in general will be found in a subsequent article in this series.

Value of the Test.

It will be seen that owing to the difficulties of interpretation the value of an estimation of the blood-urea is limited. None the less it is the simplest of the "retention" tests, and its extensive employment has led to wide recognition of its limitations. In proved kidney cases it is valuable both in the assessment of the progress of a case and as a guide to treatment. In the diagnosis of uræmia it is very useful, and there is generally little doubt as to the meaning of really high figures—e.g., over 100 mg. In doubtful cases its value is greatly enhanced if combined with an estimation of the concentration of urea in the urine, either as part of the urea-concentration test or even in isolated specimens of urine. In fact, when used as an aid to diagnosis it is a good rule always to perform urinary estimations if the blood-urea lies between 50 and 100 mg.

An estimation of urea in the blood, like the urea-concentration test, is a measure of the efficiency of nitrogenous excretion, and of that only. The remarks made in this connexion in discussing the value of the urea-concentration test apply with equal force to the blood-urea.

OTHER ANALYSES.

Uric acid and *creatinine* are retained along with urea in severe renal inefficiency. As a rule no additional information results from their estimation. The uric acid may rise to 30 mg. It is said that the prognosis is almost always hopeless if the creatinine rises above 5 mg. in chronic renal lesions.

In chronic parenchymatous nephritis (nephrosis) the blood *cholesterol* is often raised (200 to 1000 mg.), but the diagnosis is usually obvious on clinical grounds and generally the estimation gives no additional help in either prognosis or treatment. The *plasma* or *serum proteins* are often lowered in the same disease, and this fall is due much more to loss of albumin than of globulin, so that the ratio of albumin to globulin becomes lowered. The differential estimation of plasma proteins is a relatively

complicated procedure, and the results generally give no useful additional information.

In gross renal inefficiency (uræmia) the *inorganic phosphate* is often raised (5 to 20 mg.) and the *calcium* lowered (9 to 5 mg.), but from the clinical point of view their estimation is usually superfluous. *Indicanæmia* (retention of potassium indoxyl sulphate) often occurs in uræmia, and Andrewes's diazo reaction provides a simple qualitative test for this, but the reaction is only positive when the blood-urea also is raised, so that it is not likely to be used extensively. Estimations of the *alkali reserve* provide a rough measure of the degree of acidosis in severe renal disease, and may be useful in controlling alkali treatment.

DYE TESTS.

1. *Indigo-carmin*.—This test is used extensively in surgical work, and almost invariably by the surgeon himself. The dye is injected intramuscularly in amounts varying between 0.08 and 0.16 g. (20 c.cm. of 0.4 per cent. solution = 0.08 g.). Either the combined urine or the segregated urines (obtained by ureteric catheterisation) are then examined. The points to be noted are the time elapsing between injection and the first appearance of the dye, the time of maximum colour, and the time required for complete excretion. The indigo-carmin test is therefore a "time" test. Quantitative colorimetric determinations are not satisfactory. The test is used particularly in diagnosing which is the kidney affected, or in obtaining a rough comparison between the efficiency of each of the two kidneys. The following table may be useful in interpreting the surgeon's report.

—	Normal.	Abnormal.
Appearance of colour ..	5–20 mins.	Delayed beyond 20 mins.
Maximum colour	About 45 mins.	After 1 hour.
Total excretion	Complete in 14 hours.*	Delayed beyond 14 hours.

* Greater portion in 12 hours.

2. *Phenol Red* or *Vital Red* (phenolsulphonaphthalein).—This dye is used both as a "time" test (in the same way as indigo-carmin) and as a quantitative test. Injections are made subcutaneously, intramuscularly, or intravenously. The usual amount is 6 mg. (0.006 g. in 1 c.cm.).

When the test is used as a "time" test, the patient drinks enough water (about 300 c.cm. or 10 oz.) to ensure a good flow of urine. On completion of catheterisation the dye is injected, and the urine is received in a test-tube containing a few drops of liquor potassæ or soda solution (10 to 25 per cent.).

—	Normal.	Abnormal.
Appearance of colour ..	5 to 10 mins.	Delayed beyond 10 minutes.
Maximum colour	15 to 20 mins.	20 minutes.
Total excretion	Complete in 4 hours.*	4 hours.

* Greater portion in 2 hours.

When it is used as a quantitative test, the patient is instructed to empty the bladder completely (specimen 0) and to drink about half a pint of water. The 6 mg. of dye are then injected. The urine is collected at the end of one hour and again at the end of two hours after the injection. The quantity of dye in each of these specimens is estimated colorimetrically. Normally, 40 to 60 per cent. of the dye is recovered at the end of the first hour, and 15 to 25 per cent. at the end of the second hour. The total recovery in the two hours normally varies from 60 to 85 per cent. Figures below 40 per cent. (first hour) or 60 per cent. (two hours combined), suggest renal inefficiency. It should be noted that children excrete phenol red better than adults. In two hours normal children excrete 70 per cent. or more.

The phenol red test is a measure of the power of the kidneys to excrete a foreign substance. It has been very extensively used in America and to a less extent in this country. The general consensus of opinion is that it runs parallel with the blood-urea. It is subject to practically the same limitations as the latter, when used as a quantitative test.

CONCLUSION.

The examination of the patient, together with tests for proteinuria and a microscopical examination of the centrifugised deposit, remains the essential investigation of every patient. The surgeon will often extend his examination by using the dye tests in conjunction with catheterisation, and both physician and surgeon will often employ the urea tests with advantage. The remaining tests are of value in certain selected cases and in special investigations.

Special Articles.

MEDICINE AND THE LAW.

Unsuccessful Action against the Royal Microscopical Society.

MANY learned societies promote education and scientific research with financial resources which leave no great margin for unexpected expenses. One such expense is the cost of self-defence against unsuccessful claims in the law courts. An action was brought last week in the High Court against the Royal Microscopical Society, its President, and joint honorary secretaries, the claim being for damages for alleged wrongful dismissal and defamation of character. The plaintiff had been secretary for nine years, but had his employment terminated in May, 1927, on three months' notice in accordance with the terms of his engagement. He actually received three months' salary with his notice, but he had, it seems, no grievance on the ground that he had not been called upon to do work for the final months. So much for the allegation of wrongful dismissal; it was clear that the Society terminated the engagement in an entirely lawful manner. The alleged defamation consisted merely in the circumstances that the executive of the Society recommended the termination of his engagement, and that an instruction was given that this recommendation be placed on the agenda paper for the next meeting of the Council. Naturally the defence was a plea of privilege and that the words, if spoken, were spoken in pursuance of the defendants' duty without malice and in the honest belief that they were true. At the close of the plaintiff's evidence and after listening to a recital of incidents which the judge declared to be appropriately microscopical, the court held that the plaintiff had no case in law. Mr. Justice McCardie directed the jury to return a verdict for the defendants, who had not been called upon to answer the plaintiff's case. The jury returned a verdict as directed and judgment was entered for the defendants, whose counsel intimated that he did not ask for the usual costs, but for an order limiting costs to the out-of-pocket payments made by the defendants.

The history of common law claims in the English courts indicates the evolution of certain formal causes of action to which plaintiffs have been confined. The issues being strictly delimited and the evidence being restricted to what is relevant to those issues, it by no means follows that a man with a grievance has necessarily a legal remedy. By invoking the law of libel and slander, however, a plaintiff can often ventilate in the law courts some matter and can obtain the verdict of a jury upon some issue which otherwise would escape the strict legal categories of wrongs and damages. On the other hand, the rules of procedure provide for the striking out of frivolous and vexatious proceedings. It is unfortunate for a plaintiff that he should be so misguided by his legal advisers as to embark on proceedings which are found to be

unwarranted and hopelessly bad in law. It is even more unfortunate for a scientific society that, after acting with entire propriety, it should have its funds depleted by the cost of defending itself against an action which should never have been brought.

Car-hire for Patient: Doctor's Liability.

A medical practitioner, who arranged for the conveyance of a patient from Eastbourne to Balham, has been held personally liable for the cost of hiring the car. The doctor had taken the precaution of obtaining the patient's consent before telephoning the order for the motor-car. But he did not explicitly inform the car proprietors that he was acting on the patient's behalf—a fact which one might almost assume to be self-evident in the circumstances—and the omission was fatal. The county court judge declined to hold that there was any custom or usage by which it could be deemed notorious that the doctor was acting as agent; this contract for a journey of 120 miles was, said the judge, something different from ordinary routine, even if in small matters a doctor might be regarded as an agent without express statement. The car proprietors evidently preferred to sue the doctor rather than the patient, and, according to the report of the case in the *Times*, Judge Cann found two important facts in their favour. In the first place, he found that the doctor, in giving the order, did not mention that he was acting as agent; this circumstance made the doctor *prima facie* liable as a principal. Secondly, he found that the car owners did not give credit to anyone to the exclusion of the doctor, nor did they elect to rely on the credit of anyone else but him. These phrases follow the lines of leading cases on the law of principal and agent, and the findings of fact may prove significant when—as appears likely—the matter is taken to a higher court.

Nurses and National Health Insurance.

There has been some doubt whether the National Health Insurance Act applies to trained nurses who are members of an association. The proprietress of such an association was summoned by the Ministry of Health at the Marylebone police-court for non-payment of health insurance contributions. The Ministry's representative relied upon the terms of the association's rules under which the nurses were paid 12s. out of every 21s. received by the association, and were provided with board, lodging, and laundry; this, it was suggested, was a fixed wage, and a direct contract of service within the meaning of the Act. For the defendant it was argued that the nurses were merely maintained while not nursing; they were not paid wages and, therefore, were not insurable. No ruling was given on the facts or the law as the defendant apparently paid up the disputed contributions before the case came on for hearing. The Ministry's representative, not content with the satisfaction of his claim, pressed for a penalty and costs, but the magistrate merely adjourned the case *sine die*.

Powders for Cancer.

In reply to a note under this heading in our last issue Mr. Raphael Roche writes to point out that the patient consulted him on Oct. 22nd, not "last September"; that his charge of 15 guineas was a reduction on his ordinary fee of 20 guineas for a first consultation; that the patient did not "become" very sick after taking his powders, but continued to be very sick; that he did not say "the drugs I make" but "the drugs I make use of"; that he said the phosphorus in the powders could be the vital force; and finally that the form which he requires patients to sign is to the effect that he is not a legally-qualified medical (not "unqualified") man.

A LEICESTER CHILDREN'S HOSPITAL.—Roecliffe Hall, near Leicester, with 40 acres of land, has been bought by the Leicester and County Saturday Hospital Society for a children's hospital. It is intended to adopt it for the reception of 50 or 60 children, at an approximate cost of £25,000.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Pit-head Baths.

At the Dalzell and Broomside Colliery of the Glasgow Iron and Steel Company, Motherwell, an installation of pit-head baths, the first in Scotland, is to be opened on Nov. 24th by Lord Chelmsford, chairman of the Miners' Welfare Committee, under whose auspices the experiment is being made. The installation is distinctive in having accommodation for female as well as for male workers. The scheme provides for bathing accommodation, locker rooms for pit and ordinary clothes, facilities for the cleaning and greasing of pit boots, drinking fountains, filling points for water bottles, a canteen and a first-aid room.

This is the second of four demonstration baths to be erected by the Miners' Welfare Committee. The first was at Pooley Hall Colliery, Warwickshire, opened in April last, the two others now in hand are at Trerochy in South Wales and Mainsforth in Durham. Minor experiments on these lines have been undertaken by at least one of the Scottish companies; but the manager found that the men were not enthusiastic. Now that the money is available from the Welfare Committee, which was established as a result of the Sankey Commission, opinion seems to have changed, and it is hoped that this admirable new installation will appeal to the colliers.

Ten years or more ago, in a survey of the principal Scottish coal-fields, I came across two or three examples of a traditional custom among the miners—for instance, that in washing their bodies after coming from the pit they were careful not to wet the spinal column, and the result is—I have seen it in actual fact—a black streak about 2 or 3 inches wide running from occiput to coccyx. The explanation given to me was that the washing of the spinal column had a "weakening effect." I discussed the point with several miners who carried on the practice, but they could give only the traditional reason for it. One never likes to set aside as absurd, without inquiry, a well-established habit passed on from generation to generation.

A Settlement Case.

It is to be hoped that reforms in local government will make an end once for all of the endless waste of time and money of parishes over settlement cases. In the Sheriff Court at Ayr, Sheriff-Substitute Haldane has been commenting strongly on a squabble about £42 1s. 9d. He said:—

"It is no doubt a matter of great importance to the rate-paying public that poor-law relief should not be paid at their expense to persons who are not legally entitled to it from them, but I think it is at least equally important to them that parish councils should not be allowed to dissipate their funds on superfluous litigations. It is, accordingly, of more importance, in my opinion, that such a matter once decided, even if it be wrongly decided, should not be again made the subject of costly litigation than that an ideally accurate decision should be arrived at. The only apparent reason which the parish council of Girvan have for wanting to reopen the case is that their officers have all along held so strongly to their own opinion of the man's condition that they were unable to accept the decision of the Board of Health, as they agreed to do, when it happened to be adverse to them."

The question of parochial settlement has been a burning one for three generations. It cannot be reformed all at once; but I should think it probable that the new Act will put the whole of these petty problems of the small parishes on a better footing. Thousands upon thousands of pounds have been wasted in legal proceedings with no more justification than the one here commented on.

Watered Milk.

Sheriff Jameson has imposed a fine of £35 on a milk-seller guilty of three offences and previously fined £5 and £10. The milk showed 36 per cent. reduction in butter-fat and 38 per cent. added water.

In imposing the fine the Sheriff reminded the seller that the maximum fine was £100. This fine of £35 is drastic, but not beyond what these cases deserve. It is difficult to see why in this peculiarly debased form of swindling any sheriff should hesitate to impose the maximal fine. Indeed, it is a question whether traders of this type of morality should be retained in the trade at all. They might, at least, have their licences endorsed like the erring motorists.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Poor-law Salaries in County Mayo.

THE salaries paid to dispensary medical officers in County Mayo have long been a standing reproach to poor-law administration in the Irish Free State. It is one of the few counties in which there is no county scale of graded salaries. Salaries are still paid on the same basis as when the administrative area was the dispensary district, not the county. The consequence is that there is no uniformity between the salaries paid in neighbouring districts. In one district the salary is as low as £100 a year. In another the scale runs to £250 a year. On many occasions during the past six years appeals have been made to the Minister for Local Government and Public Health to intervene, and insist on the payment of adequate salaries. He has recently addressed an important letter to the County Board of Health in which he states that the salaries have never been adjusted to meet in any way the increased cost of living, as has been done elsewhere throughout the Irish Free State. He feels that a point has now been reached when in justice to the officers concerned and in the interest of the public services for which they are responsible, steps must be taken to ensure the payment of fair and reasonable salaries. He proposes that a scale of £200 a year with annual increments of £5 a year to a maximum of £300 a year should be established. The County Board should also review the salaries of the medical officers and surgeons of the county hospital and of the medical officers of the county home. It is pointed out that approximately half the expenditure of the County Board is at present borne by central funds, so that the payment of adequate salaries to the medical officers will not press unduly on the ratepayers. The receipt of the Minister's letter appears to have caused dismay among the members of the County Board of Health, and action on it was postponed, although one member admitted that the rates in County Mayo were the lowest in the country. It is hoped that the Minister will, if necessary, fix salaries by a sealed order, as he has the power to do. The hardship of medical officers in County Mayo entailed by inadequate salaries is increased by the fact that the districts are large and travelling expenses are high, while there is, in the greater part of the county, very little private practice.

Clean Milk.

A deputation from the Irish Clean Milk Society waited last week on Mr. Richard Mulcahy, Minister for Local Government and Public Health, and presented a petition begging for legislation to ensure a supply of clean milk for the Irish Free State. There were nearly 3000 signatures to the petition. In reply, the Minister assured the Society of his full sympathy with its objects, and he stated the report of the Inter-Departmental Committee on Milk was receiving careful study with the view of framing legislation on it. He would discuss the matter with the Society again in January next.

Disseminated Sclerosis.

The outgoing President, Dr. William Porter, of Portrush, took the chair at a meeting of the Ulster branch of the British Medical Association on Nov. 22nd, and introduced Dr. Foster Coates, of Belfast, as President for the session. Dr. Coates

then delivered a presidential address on disseminated sclerosis, based on a series of 106 cases treated in the medical wards of the Royal Victoria Hospital, Belfast. This series, he said, had occurred among 728 neurological admissions, a ratio of 14.5 per cent., as compared with 6 per cent. amongst the admissions to the National Hospital, Queen-square, London. The speaker was convinced that these figures represented the greater incidence of the disease in Northern Ireland, and were not the result of diagnostic errors. His inquiry into environment and occupation tended to confirm Adams's contention that the disease is commoner in country than town, but showed no marked incidence among woodworkers. He next considered the various aetiological theories which have been advanced; in considering physical signs he classified the cases into an acute remittent and a chronic progressive type, and considered the prognosis rather better in the former. He had observed one case in which there had been a remission of 11 years' duration. He briefly reviewed the various forms of treatment which have been advocated and expressed the opinion that recurrent courses of silver-salvarsan appeared to delay the progress of the disease.

Dr. A. Gardner Robb proposed, Dr. J. C. Loughridge seconded, and there was passed by acclamation a hearty vote of thanks to the President for his address.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Relative Humidity and Health.

DURING the last eight years research work of great importance has been conducted at Pittsburgh to determine what are the physical conditions of our atmospheric environment most conducive to comfort, efficiency, and health. This work has been carried out by the research laboratory of the American Society of Heating and Ventilating Engineers with the cooperation of the Federal Government through its Bureau of Mines and Public Health Service at a total cost of something like \$40,000 a year. The engineers' work, under the direction of Mr. F. C. Houghton, has been confined to studies on temperature, humidity, and air motion. The results up to date were summarised at the recent meeting of the American Public Health Association in Chicago by Mr. Houghton himself in collaboration with Mr. W. W. Teague. Much of the work reported on this occasion has already been published in the *Journal* of the A.S.H.V.E. and has been widely noticed by physiologists and sanitarians. Quite recently the laboratory has been investigating the problem of the relation of relative humidity to health, a problem which is more pressing in the winter climate of North America than it is in England. Mr. Houghton points out that when the outdoor temperature is zero with 60 per cent. relative humidity, the air indoors without humidification will have a relative humidity of 3.1 when heated to 70° F. Many furnace-heated houses in this country are kept constantly at a higher temperature than this. It is true, Mr. Houghton says, that one pound of outdoor air and one pound of hot indoor air will each extract the same quantity of moisture from the respiratory tract before being exhaled at a temperature of approximately 98°. The latter, however, has a much greater affinity for moisture when it first enters the mouth or nasal cavity, and will rapidly take a large amount of moisture from the mucous membrane near the entrance to the mouth or nose, whereas the cold air will take up moisture more slowly in passing on toward and into the lungs as it is being warmed up. It is to the need for investigation of this phase of the subject that the authors of the paper finally draw attention.

Bacteriophage and Vaccines.

Another striking paper presented to the Public Health Association this year came from the State Department of Health at Lansing, Michigan. The

immunologist of this department, Mr. N. W. Larkum, Ph.D., has during the last five years been investigating the possibilities of applying the properties of bacteriophage to public health work. He has met with considerable success, as have other workers, in treating staphylococcal infections from furunculosis to osteomyelitis. He points out that bacteriophage-lysed cultures can produce all the antibodies obtained by use of an ordinary heat-killed vaccine and that the former will also increase the opsonic index to a remarkable degree. Using lysed cultures of *Bacillus typhosus* and *B. paratyphosus* A and B, Mr. Larkum finds that large doses can be given to human subjects without any general reaction resulting and with only a slight local reaction. Agglutinin production in the subject takes place to the same degree, but more rapidly by this new method. The technique for producing this new vaccine is very simple and inexpensive. Up to the present no antiseptic has been added to the vaccine as a preservative, since none has been found which is innocuous to the bacteriophage. It is not clear, however, that destruction of the phage would in any way diminish the antigenic value of the vaccine. Mr. Larkum has avoided antiseptics merely because this "destroys the possibility of using the bacteriophage for treatment."

* Excluding dental defects and uncleanness. —† Not stated.

Bristol.

IN Bristol there are special schools of all the usual types, including those for myopes and the partially deaf, so that the return of exceptional children shows unusually few who are "still attending elementary school" or "at no school or institution." The only provisions still needed appear to be a residential open-air school and some accommodation for epileptics. Orthopaedic work is well organised. Mr. H. Chitty, orthopaedic surgeon to the committee, conducts a clinic at the Red Cross-street special school, for which an additional masseuse and up-to-date apparatus have been recently provided. Much of the medical work consists in the provision of surgical boots and appliances; constant supervision is necessary to keep these in good repair and to effect necessary alterations as the children grow or their conditions change. Operations on children attending the clinic have been performed either to prevent or to cure deformities or with the object of dispensing with cumbersome surgical appliances. In most cases the results have been very successful, and there are few children whose general condition has not markedly improved since they commenced to attend the clinic.

The cost of apparatus is borne by the parents, by the Education Committee, and by the Bristol Cripple Children's Society. This society has also helped to send 14 children to open-air hospital schools and 71 to other hospital convalescent homes. It is hoped that a start will soon be made on the erection of a special

voluntary hospital for orthopaedic cases at Winford. Much attention has been devoted to infantile rheumatism and heart disease, and Dr. R. A. Askins gives a table showing the percentage of deaths from heart disease to total deaths from 1921 to 1927:—

	1921	1922	1923	1924	1925	1926	1927
Percentage of total deaths	12.38	12.01	13.27	14.02	13.1	14.82	16.26

These figures show a marked increase, and apart from loss of life there are the long periods of invalidism and incapacity for work from their cause. He estimates that a quarter of the total deaths from heart disease are due to rheumatism arising during school ages. In 1923 began the investigation by Dr. Carey Coombs and Dr. C. Herapath which led to the elaboration in 1927 of a definite scheme. A clinic has been established in the University Centre of Cardiac Research at the Bristol General Hospital under Dr. Carey Coombs, and all cases of rheumatic infection in any form and of non-rheumatic heart affections in children are invited to attend. In addition the medical practitioners in Bristol have been asked to notify cases and an admirable response has been obtained. The objects are: (1) expert early diagnosis; (2) treatment (including regulation of school curriculum); (3) research into causation, including house visits by medical officers of the school medical service to the homes to inquire into environmental conditions and family history. Dr. Herapath is doing similar work for the Somerset Education Committee. The whole scheme seems to be an excellent example of coöperation between hospital consultants, general practitioners, and the school medical service.

Eastbourne.

The proportion of children of school age is low in Eastbourne and is progressively diminishing. In 1891 it was 21.19 per cent. and in 1921 it was only 16.40 per cent. of the total population. Many of the children are residents at boarding schools, so that the number attending elementary schools is very small—less than 5000—but the provision for treatment of defects and for the care of exceptional children gives an example of what can be done.

Clinics are held for minor ailments, eyes, throat and ears, teeth, ringworm, tuberculosis, and malnutrition and for orthopaedic cases, as well as the examination clinic for mentally abnormal children. The orthopaedic clinic has the service of a visiting consultant, Mr. J. B. Barnett, and much help is given by the "Tiny Tims" clinic run by a voluntary society. There is no special school for cripples, but their number in Eastbourne appears to be very small. Very satisfactory results are obtained both at the special mental defective school largely through the personal influence of the head mistress, and at the open-air school formed by the alteration of army huts in 1920, where the marked gain in physical well-being has enabled many previously delicate children to return to the ordinary school to compete on equal terms with the other children. The fact that in a town like Eastbourne, with its environmental and climatic advantages, open-air school accommodation is deemed necessary for 75 children shows how much greater is the need for such provision in many industrial towns where no such facilities exist. There are in Eastbourne only ten abnormal children not attending any school, and of these two are crippled inebiles and the other eight are under regular treatment. Captain Stainfield was appointed organiser of physical training in 1923, and Dr. W. G. Willoughby emphasises the value of his work on the health of the children, and endorses the view that physical training should be carried out in the open air whenever possible.

Leeds.

The report of Dr. Algernon Wear on the school medical work in Leeds is accompanied by many tables, which show how great and varied are its activities; these were, nevertheless, curtailed by the shortage of medical staff due to an unfilled vacancy

and unavoidable absences on account of sickness. The number of routine inspections outside the age-groups has fallen and there has been a partial cessation of the special inquiries, while the liaison work between the tuberculosis department and the school medical service has suffered. Similarly, there has been an unfilled post in the dental staff, so that six dental clinics have had to be worked by five full-time and one part-time officer. The low percentage of those treated to those requiring attention (59.2 per cent.) is, however, less attributable to this shortage than to parental indifference. The institution of casual sessions for cases of toothache is undoubtedly an immediate boon to the sufferer, but there is a danger of the parents relying too much on this expediency and failing to appreciate the need for conservative treatment. The general level of nutrition shows a slight improvement on last year, and Dr. St. Clair Stockwell has made use of the formula $Q=W \div H$ which is very convenient for practical purposes, although many authorities have shown that it is not reliable for accurate scientific investigation. In spite of the improvement there is a very large number (910) of children urgently needing the régime of an open-air school, many of them entirely out of school, and many more who will go to swell the number of chronic invalids in later life, including especially the tuberculous. At a joint meeting of representatives of the education and health departments it was unanimously agreed that an open-air school was a necessity, and Dr. Wear visited Newcastle to see the Pendowes open-air school. In this matter Leeds is notably behind most other authorities, for the nearest approach at present to any provision for open-air education is the small camp school at Ilkley mentioned in the interesting report of Mr. Jarman, the organiser of physical education. Some special inquiries were carried out. One dealt with the influence of locality on lung affections, and showed that there is a much greater prevalence in schools in low-lying districts than in those in higher altitudes (9.9 per cent. as against 4.7 per cent.) and for bronchitis alone the difference was even greater. Another inquiry concerned the influence of previous infectious disease upon the number of defects found at routine inspections; the results pointed to the interesting conclusion that attacks of the exanthemata lessened the tendency to later defects.

Stockport.

Considering its size there are not many facilities for dealing with exceptional children in Stockport, but it is evident that under Dr. N. Gebbie full use is made of whatever is available, and in stating the needs for extensions only the most urgent matters are set out. There are no special schools of any kind in the borough, but a fair number of mentally defective, deaf, and blind children are sent to outside institutions. There are 537 delicate children still attending elementary schools, but it is hoped that a scheme will be brought forward at an early date to provide some open-air educational facilities; meanwhile good work on a small scale has been done through voluntary bodies such as the George Fearn Trust, which sent some 97 children in the past year to residential open-air schools. There is no physically defective school, nor an orthopaedic clinic under the authority itself, though the committee has accepted financial responsibility for children requiring orthopaedic treatment at the Stockport Infirmary, where artificial sunlight treatment has just been installed. Some cases have also been sent to the Shropshire Orthopaedic Hospital at Oswestry. The pressing necessity for further dental help is realised; already a great deal of the dentists' time has been taken up by "casuals," thus seriously encroaching on the time that should be available for routine inspection and treatment. There is manifestly here something of the nature of a vicious circle, for the less completely it is possible to carry out proper routine inspection and treatment the larger will be the number of casuals, and the more casuals there are the less possible it is to carry out dental work in the best sense. The only remedy is to have an adequate

staff and to eliminate the casuals or at least render their number relatively unimportant, and the fact that the parents are at last beginning to lose their apathy makes the need for improved facilities all the more essential. With a complete dental scheme there will be, as has been demonstrated in some other parts of the country, a steady increase in the number of children with sound teeth with marked benefit to their general health, and ultimately an actual reduction in the amount of dental work required.

Swindon.

Dr. Dunstan Brewer remarks that each year it becomes more anomalous to describe the health of the school child separately from that of the general population. A strong link is being forged by the development of infant welfare work; many of the defects and diseases which were formerly discovered in the examination of school entrants are now recognised and dealt with at an earlier stage. Looking forward Dr. Brewer sees the main function of the school medical service to consist in determining the kind of education for which the child is fitted. In inculcating health as a positive function—a task in which the teachers should be partners—he mentions appreciatively the Board of Education "Handbook of Suggestions in Health Teaching" and the journal *Better Health*, issued by the Society of Medical Officers of Health. He says that some types of defect tend to maintain almost a constant level, but others will be affected by the extended treatment of infants and others by such means as the ionisation treatment of ear disease and the thallium method for ringworm described in some detail by his assistant, Dr. G. W. Fleming. In the treatment of ear disease a great advance has been made by the recent establishment of a special clinic under Mr. Kenneth Lees. In dental work good progress is being made. Already the fillings of permanent teeth greatly exceed the extractions, and it is probably quite true that the time will come when the removal of a tooth will be looked upon as an exceptional procedure and "eventually considered a malpraxis."

Special investigations describe: (1) Inquiry into ventilation in schools by the use of the katal thermometer (Dr. Fleming). (2) An account by Dr. V. Redman King of the social and physical conditions of 104 children suffering from tonsils and adenoids, who have been known from birth. The results so far seem to show no relation to breast-feeding or housing conditions. (3) The connexion between multiple hair vortices and the mental condition was investigated. These vortices were found in 6 per cent. of ordinary children, and they were not more frequent in the few mentally defective children in Swindon. Hence the presence of these vortices, one of the so-called stigmata, is of scarcely any value as evidence of mental deficiency.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED NOV. 17TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox 162 (last week 149); scarlet fever, 3002; diphtheria, 1444; enteric fever, 61; pneumonia, 976; puerperal fever, 45; puerperal pyrexia, 125; cerebro-spinal fever, 8; acute poliomyelitis, 12; encephalitis lethargica, 21; dysentery, 10; ophthalmia neonatorum, 97. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Nov. 20th–21st was as follows: Small-pox, under treatment 20, under observation 1; scarlet fever, 2692; diphtheria, 2954; enteric fever, 24; measles, 73; whooping-cough, 312; puerperal fever, 15 (plus 10 babies); encephalitis lethargica, 71; poliomyelitis, 3; "other diseases," 15. At St. Margaret's Hospital there were 12 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 19 (0) from measles, 5 (0) from scarlet fever, 19 (4) from whooping-cough, 37 (8) from diphtheria, 73 (18) from diarrhoea and enteritis under two years, and 72 (12) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever outside London occurred at Middlesbrough. Sunderland reported 5 fatal cases of measles and Newcastle-on-Tyne 3. Two fatal cases of whooping-cough were reported from each of Birmingham, Liverpool, Manchester, Salford, Leeds, and Middlesbrough. Liverpool reported 7 fatal cases of diarrhoea, Manchester 6, Birkenhead and Sunderland 4 each; while for the same week the figures for Glasgow, Dublin, and Belfast were 7, 6, and 4 respectively. Influenza claimed 4 deaths each in Birmingham and Middlesbrough, 3 each in Warrington, Leeds, and Rhondda.

The number of stillbirths registered during the week in the great towns was 278 (corresponding to a rate of 43 per 1000 births), including 58 in London.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

J. J. Benson, R. Russell, and J. Y. Woodhouse to be Surg. Lts.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lts. S. B. Borthwick to be Surg. Lt.-Commdr., and E. E. Stabler to Victory, for R.N. Hospl., Haslar, for training. Surg. Lt. (D.) G. R. D. Hankinson to Victory, for R.N. Hospl., Haslar, for training.

Proby. Surg. Lt. H. P. Widdup to Victory, for R.N. Hospl., Haslar, for training.

ROYAL ARMY MEDICAL CORPS.

Cpts. W. Millerick and E. O. A. Singer to be Maj. Lt. (on prob.) H. W. Daukes, from the secd. list, is restd. to the estab.

Cpts. J. G. Bird and Jal Edalji Dhunjibhoj to be Maj. Lts. A. Rosenbloom, M. P. Conroy, W. J. Shipsey, and Chiranji Lal Pasricha to be Cpts.

Temp. Lt. Prabhakar Narayan Gokhale relinquishes his temp. comm.

FREE MILK DAILY FOR SCHOOL-CHILDREN.—On Nov. 19th the Lancashire Education Committee approved a recommendation of the school medical subcommittee authorising the county medical officer to supply a pint of fresh milk on each school day to every child in Westhoughton schools who is suffering from malnutrition and whose parents are not in a position to provide the necessary nourishment; also to provide cod-liver oil and malt to children who require special nourishment. It is stated that to provide a child with a pint of milk on every school day will cost 55s. a year, and to provide for 10 per cent. roughly the proportion regarded as suffering from some degree of malnutrition—would mean an expenditure of £32,000 for the county. To begin with, it is proposed to take one-eighth of the county for the three winter months. This will cost £1183, and it is proposed to spend roughly some £387 on cod-liver oil and malt.

GENERAL MEDICAL COUNCIL.

PRESIDENT'S ADDRESS.

At the winter session of the General Medical Council which opened on Nov. 27th the President, Sir DONALD MACALISTER, began his address with a brief sketch of the place and function of the Council in the State.

The Council's Place and Function.

On Nov. 23rd, 1858, 70 years ago, said Sir Donald, the General Council of Medical Education and Registration first met, in the Hall of the Royal College of Physicians, pursuant to a summons by the Secretary of State. Sir Benjamin Brodie was elected the first President of the Council, and Dr. Francis Hawkins the first Registrar, and committees were appointed for the conduct of business, for registration, and for the National Pharmacopœia. It does not appear that the President delivered an opening or any other address to the Council. I have sometimes wished that this precedent had been followed by his successors. But it is recorded that in a dignified communication, with reference to a proposed petition by the Council to the Government of the day, he stated his view of the functions and relations of the new Council in these terms :—

"The Medical Council is appointed by Parliament to act in those matters which affect the medical profession, both on the part of the profession and of the public. It is not to be supposed that they have any interests of their own to serve; and it is as much out of their way to proceed by way of petition as it would be for the Board of Trade to do so. Where they conceive that any alteration is required in laws concerning the profession, it is their duty to represent this in the proper quarter, not as petitioners, but as coadjutors of the Government in one department of the public business."

That conception of the Council's place and function in the State has, Sir Donald remarked, been sustained, I think worthily, for 70 years; and it has underlain the several statutory changes which in the interval have modified in various ways the legal constitution and powers of the Council as a public body. I do not propose to survey these changes in retrospect, for they have not altered the essentials of the Council's statutory relations to the public or the profession. It remains the law-appointed guardian, in the public interest, of professional education and professional behaviour, the coadjutor of the Government in its own domain. The officers of the Council propose to celebrate the seventieth anniversary by a domestic dinner to present and past members, to be held during this session.

Some Recent Losses.

Death has been busy since we last met in May, said the President, and in a few words he set out the merits of some whose presence at their board would be missed.

Sir James Hodsdon passed away suddenly and untimely on his way home from our last session. An able and conscientious member since 1906, he had won the confidence of his colleagues for his zealous devotion to all the tasks that fell in increasing number to his share. Sober and cautious in judgment, his opinions were not hastily formed, and they carried the weight which always attaches to sincere and well-matured utterances. His long services to the Council and to the Scottish Branch will not lightly be forgotten.

Sir Arthur Chance also, brilliantly critical at times, but always helpful, contributed much during the last 13 years to the efficiency of our labours, and the interest of our debates. To his wisdom and foresight during the discussions on our relations with the Irish Free State, the working agreement which is now operative was largely due.

Sir Charles Tomes for 22 years was a Crown member of the Council, appointed in the interest of dental surgery. His scientific and professional eminence in that speciality, together with his wide knowledge in other branches and his competence in finance, gave

him a unique place in our counsels. The Council for 16 years profited by his sagacity as treasurer during the difficult time of transition to our present building, and of complications due to the war. He also, as a trusted adviser of the Government, had much to do with shaping the Dentists Act of 1921, and of preparing the way for the devolution of certain of our duties as regards dentistry to the new Dental Board.

Sir Nestor Tirard was for only five years a Crown member of the Council itself; but his intimate connexion with its work on successive Pharmacopœias extended over 33 years. As secretary of the Pharmacopœia Committee he assisted in the editorial preparation and supervision of the issues of 1898 and 1914, and of the Addendum of 1900. I can speak, perhaps better than any other, of the capable and unselfish manner in which during that time he assisted me as chairman of the committee, and of the wide and varied knowledge of the subject matter which he acquired and applied to his duties. The British Pharmacopœia, 1914, of which he was senior editor, will remain as a monument to his mastery of pharmacopœical science and practice.

Sir Hector Clare Cameron has just died full of years and honours at the age of 85. One of the last survivors of Lord Lister's personal assistants and coadjutors—he has fitly been described as Lister's "beloved disciple"—he held a high place not only among Glasgow celebrities, but in the affectionate regard of the surgeons of the world. To myself his loss is irreparable, for from the time when in 1889 he first welcomed me to this Council as a colleague, until the end, he was my unfailing friend and counsellor, on whose kindly wisdom and manifold experience it was ever my privilege to draw.

New Members.

But while we miss and mourn these veterans, with grateful acknowledgment of what they were and did for us, we may be thankful, Sir Donald went on, that there is never wanting a supply of good and faithful men to take their places. Thus, in the room of Sir James Hodsdon, the Royal College of Surgeons of Edinburgh has appointed Dr. Alexander Miles, eminent as a surgeon and a surgical teacher in that famous school, honorary doctor of laws, and joint editor of the *Edinburgh Medical Journal*. And in the room of the late Dr. Macdonald, and of Sir Robert Bolam, transferred to the University of Durham, the registered practitioners resident in England and Wales have elected by overwhelming majorities Mr. Ernest Kaye Le Fleming, of Wimborne, and Mr. John Wardle Bone, of Luton, as their Direct Representatives on the Council.

India.

The President went on to speak of the relations with the Government of India, on the question of the recognition for practice in this country of Indian medical degrees. These are, he said, approaching a more stable and satisfactory position. A Bill for establishing an All-India Medical Council, which will exercise effective supervision over professional teaching and examination in the Provinces, having special regard to the external and central or non-provincial aspects of medical qualification, is now under discussion by the Central Legislature. And a proposal for the appointment in the meantime of a central Commissioner of Medical Qualifications and Standards has been approved by the Government of India and by the Provincial Governments. We may hope, therefore, before long to be able to conduct our negotiations and inquiries regarding the recognition of particular Indian degrees through a central Indian body or officer, whose reports we may accept as authoritative. It is much to be desired that the Commissioner appointed should be familiar with British standards of qualification, as well as with those current in India. For the essential consideration for the Council is the maintenance of substantial equivalence between the two. Our primary interest is that recognised Indian medical degrees shall guarantee a standard of proficiency sufficient for practice in this

country. It is this interest, which we cannot forgo, that alone justifies our intervention in Indian medical education. In the meantime, the Executive Committee, after considering the reports received from the Indian universities (including Calcutta) concerning their progress in education and examination, have agreed to recognise their degrees for another year, subject to further inspection of their qualifying examinations during the current session, by inspectors appointed by the Government of India and approved by the Council.

New Zealand.

New Zealand has, by recent legislation, raised a question regarding reciprocity which is receiving serious consideration. Hitherto, New Zealand medical degrees, under an agreement of many years' standing, have been recognised for registration in this country on the condition that all medical practitioners of Great Britain were registrable without further examination in the Dominion. By an Act of the Dominion Parliament, passed without notice to the Council, such registration in New Zealand is in future limited to practitioners who hold a medical qualification granted in this country. If this limitation were accepted it would mean that New Zealand graduates registered in the United Kingdom would be free to practise not only here but in all the British Possessions and foreign countries with whom we stand in relations of reciprocity, but only *certain* practitioners on the British Register would have the like privilege in New Zealand. The Dominion Government suggest that a new arrangement might be made, by which the privileges of New Zealand graduates might be limited to the United Kingdom only. This would seriously affect the whole system of Imperial and foreign reciprocity which has been established under the Medical Act, 1886, and we are advised that it would require new legislation amending that Act. A memorandum on the subject has been prepared for submission to His Majesty in Council, who has power to declare whether the New Zealand arrangements can be regarded as "just" to the medical practitioners of the United Kingdom. If under the present law the new conditions are not held to be "just" it will be for the Privy Council to order that Part II. of the Medical Act, 1886, shall be deemed no longer applicable to New Zealand. It is probable that the opinion of the law officers of the Crown may be taken on the scope and bearing of the Act as hitherto interpreted. If it proves, Sir Donald remarked, that the Act does not admit the serious limitation proposed by New Zealand, the recent legislation in that Dominion will have to be amended, or New Zealand graduates must forgo the advantages of British registration.

The Pharmacopœia.

The proposals contained in the Report of the Committee on Civil Research, on the subject of the revision of the British Pharmacopœia, approved and adopted at the Council's last session, have been carried into effect by the Pharmacopœia Committee. A selection committee, consisting of members nominated by the Council, the Medical Research Council, and the three pharmaceutical societies, has been constituted, and has carefully considered the composition and membership of the Pharmacopœia Commission, to which the preparation of the draft Pharmacopœia will be entrusted. The Commission will consist of seven members, including a chairman, possessing expert knowledge of the several subjects and branches of pharmacopœial science—medical, pharmacological, and pharmaceutical. The several members will act as chairmen, and representatives on the Commission, of special subcommittees of reference on the different departments of knowledge and practice concerned in the framing of the Pharmacopœia. In this way it is hoped, the President concluded, that the fullest information may be gathered, from a wide field of experience and science, and that the Commission will have at its disposal, and harmonise into a

consistent and comprehensive whole, all that is necessary for the revision of the old and the preparation of the new British Pharmacopœia.

At the conclusion of his address a vote of thanks to the President was proposed by Mr. A. F. SINCLAIR and seconded by Sir NORMAN WALKER. The Council then passed to the consideration of penal cases.

APPOINTMENT OF THE PHARMACOPŒIA COMMISSION.

The Pharmacopœia Committee of the Council met on Nov. 28th. It was announced that the personnel of the Commission to whom the duty of preparing a new Pharmacopœia is to be entrusted has now been settled. It will be remembered that in May of this year (see *THE LANCET*, 1928, i., 1086) a report was issued by a subcommittee of the Committee of Civil Research, wherein it was recommended that a selection committee consisting of nominees of the G.M.C. (4), the councils of the Pharmaceutical Societies of Great Britain, of Ireland, and of Northern Ireland (3), and the Medical Research Council (2) should be charged with the duty of selecting persons to form a new body to be designated "The Pharmacopœia Commission." The members of the Selection Committee were Sir Humphry Rolleston (president), Sir Farquhar Buzzard, Dr. H. H. Dale, Sir Walter Fletcher, Mr. Leathes, Mr. Skinner, Mr. Neathercoat, and Mr. Edmund White, the last named having died before the committee had concluded its business. This representative committee has gained the consent of the following persons to serve on the Pharmacopœia Commission:—

Dr. A. P. Beddard, Consulting Physician to Guy's Hospital.
Mr. R. R. Bennett, F.I.C., Technical Director of British Drug Houses, Ltd. and Chairman of the British Pharmaceutical Conference.

Dr. J. H. Burn, Director of the Pharmacological Laboratory of the Pharmaceutical Society of Great Britain.

Dr. F. R. Fraser, Director of the Medical Professorial Clinic and Physician to St. Bartholomew's Hospital.

Prof. H. G. Greenish, D.Sc., Pharmaceutical Editor of the British Pharmacopœia, 1914; Dean of the School of Pharmacy.

Dr. J. A. Gunn, Professor of Pharmacology in the University of Oxford.

Mr. T. Tickle, F.I.C., Public Analyst to the County of Devon.

Documents and other accumulated information in the possession of the Pharmacopœia Committee will be placed at the disposal of the Commission, and it is hoped that no time will now be lost in carrying forward the process of revision, which has been in hand for some years.

BOOKS AS FOMITES.

To the Editor of *THE LANCET*.

SIR,—In a recent annotation (*THE LANCET*, Nov. 17th, p. 1036) you summarised the brief statement on the conveyance of infection by books, contained in the report of the Consultative Committee of the Board of Education on Books in Public Schools. This statement does not give any details of the recent work on the subject which has been devoted to the recovery of the specific streptococcus from fomites in cases of scarlet fever—e.g., (a) U. Friedemann and H. Deicher (*Deut. Med. Woch.*, 1926, lii., 2147)¹ found the scarlet fever streptococcus in the walls, beds, curtains, and other objects used in the sick room of scarlet fever patients, and came to the conclusion that his results "underline the necessity of a thorough final disinfection of the sick room in a case of scarlet fever." (b) A. R. Balmain (*THE LANCET*, 1927, ii., 1128) found that in artificially infected books the *Streptococcus scarlatina* could survive for 18 days even in lightly infected books. (c) B. Fejgin (*C.R. de*

¹ See *THE LANCET*, August 4th, p. 216.

la Soc. de Biol., 1928, xcvi., 118) confirmed the latter's results. He also investigated books naturally infected with scarlatinal streptococci, and his conclusion was that "books handled by scarlet fever patients harbour the germs and are capable of contributing to the spread of scarlet fever. It is necessary to avoid all contact with these books for at least six weeks and even after this period it would be best to disinfect them." (d) The Ministry of Health's Pathological Laboratory (Chief Medical Officer's Report, 1928) found that:—

"In books used by 3 children out of 15 who sickened with scarlatina, hæmolytic streptococci were found. Books used by 12 children who developed diphtheria were also examined. In one instance virulent diphtheria bacilli were isolated."

It is impossible to prove that fomites spread such an endemic disease as scarlet fever, but at present the safest conclusion would be that stated at the discussion on the subject by the Society of Medical Officers of Health that in the light of uncertainty definite measures should still be taken to prevent the possibility of the spread of infection by this means. The legal position of a library which issued books which had been in the possession of scarlet fever patients would be an invidious one, if no precautions had been taken.

I am, Sir, yours faithfully,

A. H. G. BURTON,
Medical Officer of Health, Ilford.

Nov. 27th, 1928.

A TUDOR ACT OF INDEMNITY FOR UNQUALIFIED PRACTICE.

To the Editor of THE LANCET.

SIR,—Those of your readers who saw the account of a Tudor Act of Indemnity for Unqualified Practice in your last issue (p. 1113) may like to know that Morfew is noted in Johnson's Dictionary as Morpew; morphea in low Latin meaning a scurf on the face. Du Cange says *est species scabiei*. Probably the term would be used to denote a large variety of dermatological conditions.

I do not know what "Saucelim" means; but Sir Arnold Lawson is, I believe, right in saying that "Webbe" is cataract. I believe the word "pin" is also sometimes used to denote cataract, but more frequently, perhaps, a speck or nebula of the cornea. When we remember that to the laity even to-day a corneal scar is frequently spoken of as a cataract, we can forgive our predecessors in the time of Henry VIII., for any mistakes of this nature.

I am, Sir, yours faithfully,

R. R. JAMES.

London, Nov. 23rd, 1928.

To the Editor of THE LANCET.

SIR,—The report at p. 1113 of the discovery in the Muniment Room at New Romney Town Hall of a printed copy of the Statute 34 & 35 Henry VIII., c. 8, will no doubt bring you letters from many medical historians. The words undeciphered are all in one sentence, which reads after "rootes and waters" . . . "and the using and ministering of them to such as ben peyned with customable diseases; as women's breasts beyng sore, a pin and the webbe in the eye," &c.

The Statute is directed not against all qualified practitioners, but only against surgeons, and the preamble is certainly a gross libel. It was only two years before that the barbers and surgeons had been made of one company by the Act 32 Henry VIII., c. 42, which defined the respective spheres of barbers and surgeons, and gave authority for the instruction of surgeons in anatomy. Why then this sudden attack on the whole body of surgeons? The answer is that the surgeons had unwisely pressed their powers of suing unlicensed practitioners. Thomas Gale, a member of the Barber Surgeons Company (he was Master in 1561), was very zealous in this direction, and in 1542 we find him suing unqualified persons for practising surgery, when all that they were doing was, or appears to have been, ministering rootes and waters in cases of women's breasts being

sore, and for sore eyes and sore mouths "onely for neyghbourhood and goddes sake." Paper No. 1255 of the Collection of Letters and Papers of this year, 34 Henry VIII., contains an account of how

"Agnes Guy wyff of Thomas Guy was suyd for helyng of women's papes.

"Itm. Agnes Mason wydow was suyd for the same cause.

"Itm. Katryne Bownington wyf of Richarde Boonington was suyd for gyvng water to yonge chyldren to hele cankers in ther mothes.

"Itm. John Margetson on of the Kinge's Maj's. brewers was suyd for gyvng water to clesne mens yeece (eyes).

"All these persons were suyd in the gylldhall in London Sir Rolande Hyll Knyght beyng sherefie by Thomas Gale barber surgeon which persons and divers others be now in suyte agayne in the King's Bench for the same cause."

It was this troubling of "divers honest persons" which caused the pendulum to swing violently away from the movement of 1540, and so statutory permission was given for unqualified persons to undertake certain kinds of outward treatment which was part of the province of the surgeons. The herbalists got no authority by this Act to practise for gain, and they had to be careful to keep to the special diseases mentioned. So also had any physician, if he had not been licensed by the College of Physicians (see Butler's Case, Cro. Car. 256).

With regard to the diseases questioned: (a) "Pin" belongs to the next phrase, "Pin and web in the eye," a popular name for an opacity of the cornea; (b) "Saucelim" for "saucelime," a swelling of the face accompanied by inflammation and pimples; (c) "Morpew," a leprous or scurfy eruption. James Cooke's "Marrow of Surgery" gives: "Alpha, called Morpew, great spots in the skin, changing its colour, joined with a certain roughness." He mentions two kinds, white and black morpew.

I am, Sir, yours faithfully,

FRED BULLOCK, LL.D.

Red Lion-square, W.C., Nov. 23rd, 1928.

PIN, WEBBE, AND MORFEW.

To the Editor of THE LANCET.

SIR,—The other day I sent you some extracts from my favourite pharmaceutical authority, the Countesse of Kent. This admirable woman was doubtless one of the leaders of those who gave of their "cunninge . . . to the poore people onely for neyghbourhood and goddes sake, and of pitie and charitie." She does not give a definition of Pin and Webbe, but she tells us plainly how to cure them.

For a Pin and Web in the Eye.—Take the white of an Egg, beat it to oyle, put thereto a quarter of a spoonful of English Honey, half a handful of Daisie leaves, and in winter the roots, half a handful of the inner rind of a young Hazle not above one yeares growth, beat them together in a Morter, and put thereto one spoonful of Womans Milk, and let it stand infused two or three houres, and strain all through a cloth, and with a feather drop it into the eye thrice a day.

Again:

For a Pin or Web in the Eye.—Take two or three Lice out of ones head, and put them alive into the eye that is grieved, and so close it up, and most assuredly the Lice will suck out the web in the eye, and will cure it, and come forth without any hurt.

Pin and Webbe almost certainly referred to corneal ulcers of various kinds, one prescription is for "a Pin and Web, and rednesse of the Eyes." "Morpew" is fully described as "A yellowish scurfy matter that lodges within the skin upon the upper part of the faces of many women while they are with child and some young children."

I am, Sir, yours faithfully,

H. CAMERON KIDD.

Emsworth, Hants, Nov. 23rd, 1928.

To the Editor of THE LANCET.

SIR,—The diseases mentioned in the Tudor Act of Indemnity for Unqualified Practice in your issue of Nov. 24th may be indicated from the following.

words found in the "Canterbury Tales": (a) *Pynen*—to torment, hurt, &c.; "pin" is possibly derived from this verb. (b) *Sawcefleem*—pimply, spotty, &c.; *saucelim* may be derived from this adjective. (c) *Morman*—ulcer, sore, &c.; *morfew* may be akin to this. Describing the Cook in the Prologue:—

"But greet harm was it, as it thoughte me,
That on his shine a morman hadde he."

I am, Sir, yours faithfully,

A. G. G. THOMPSON.

Brixton Hill, S.W., Nov. 26th, 1928.

A CORONER ON UNQUALIFIED PRACTICE.

To the Editor of THE LANCET.

SIR,—Your medico-legal correspondent set out last week the remarkable facts revealed at an inquest on the body of an old man who had died of cancer after being treated by an unqualified practitioner. The story shows the familiar features of credulity on the part of a suffering patient, and that blend of confidence, ignorance, self-deception, and rapacity which is common to most successful unqualified practitioners. It is rather the coroner's comments that will occasion surprise. The practitioner of medicine is well enough aware that in the average lay mind unorthodox treatment is regarded with a respect often withheld from the recommendations of his own profession. There are among the public many individuals, even among the well informed, always ready to credit the stories of miraculous cures so long as these are obtained at the hands of people who have made no study of medicine or surgery. What I was not prepared to find is a coroner apparently doing his utmost to justify and support this kind of mistaken confidence. I should have thought that a coroner in the course of his experience would arrive at the true estimate of pretentious unqualified practice. I should expect him to have some understanding of the false hopes which these people inspire and the unfair emoluments which they abstract from the credulous. I should expect him to know that, although the genuine medical man often makes mistakes, they are trivial in number and in degree compared with the colossal blunderings of the quack. In this case, at any rate, such natural expectations would be disappointed. The coroner in question was impressed by the list of names of patients who had consulted the quack, "a very distinguished list" he observed. "Have you cured cancer by the same method which you attempted on Mr. C.?" he asked. The answer was "Yes, I have cured many terrible diseases by my methods." The list and the answer were enough. The quack, he pointed out, was a "well-known man," and had been consulted by a "great many well-known people." "One cannot shut one's eyes to the fact that in many cases cures have been made by persons outside the medical profession." A coroner who makes a solemn pronouncement of this kind ought to be prepared to relate the cases and show that they were indeed cures. Perhaps he is prepared to do so. Incidentally, I should like to hear his pronounced opinion on a qualified medical man who charged 15 guineas for one consultation at his house, and two packets of cane-sugar sent by post.

I am, Sir, yours faithfully,

J. BLOMFIELD.

St. Mary's Mansions, W., Nov. 22nd, 1928.

ALLERGIC DISEASES.

To the Editor of THE LANCET.

SIR,—In the paper by Dr. Oriel and myself, published in your last two issues, no reference was made to Dr. James Adam's book on Asthma or to the writings of Haseltine and La Forge. This was a very serious omission for which I am alone responsible, and I should like to express my regret to Dr. Adam in your columns, as I did privately, when I read his book some weeks ago, by which time our paper was

already in the proof stage. Not only do the observations of Dr. Adam and of his followers confirm very largely the conclusions at which Dr. Oriel and myself have independently arrived, but in his chapter on the blood and urine Dr. Adam records some biochemical investigations, made for him by Mr. John Middleton, which anticipated some of our findings. The literature concerning allergic diseases is so vast that no attempt was made in our paper to present a complete review of it, but I am more than sorry that I should have omitted to pay tribute to Dr. Adam's invaluable pioneer work.

I am, Sir, yours faithfully,

H. W. BARBER.

Devonshire-place, W., Nov. 26th, 1928.

AN EXPIRATORY VALVE.

To the Editor of THE LANCET.

SIR,—May I venture to suggest that the valve for anæsthetic administration, described by Dr. C. Langton Hewer in THE LANCET of Nov. 17th, would have been greatly improved by the incorporation of a fitting which I described in your columns¹ five years ago—viz., a tube from the expiratory valve to lead away the expired gases? With this "exhaust-pipe" connected to a suitable tube leading to any convenient window, one of the chief objections to the use of ethylene is removed, as, if the mask fits properly, the somewhat objectionable smell of the gas is not perceptible in the operating theatre.

I am, Sir, yours faithfully,

Wimpole-street, W., Nov. 22nd, 1928. R. J. CLAUSEN.

"FEE-SPLITTING."

To the Editor of THE LANCET.

SIR,—In my recent law case to which Dr. O'Connor made reference he stated that in my evidence that I said that patients were sent to me by many leading specialists and that we shared the fees. I did say that my patients were sent to me by many eminent medical men, but I did not say (neither was it even reported in this connexion) that we shared the fees, which would have been untrue. I have never shared any fees at all with any single medical man in my life. In connexion with the proposed rejuvenation partnership for joint treatment with a particular person, there was a question of sharing fees. But this statement which I made in this connexion had nothing whatever to do with my curative treatment which I give to patients sent to me by medical men in the ordinary way. In order to refute the idea that preoccupation with what was called the "golden vision" had, or would have, upset plaintiff's cure. I told the judge that it was not to be a rhythm partnership or interfere in any way with my usual treatment—that I was to give the physical exercises at the Radiant Health Institute for rejuvenation in the same way as I did to patients sent to me by medical men, mentioning three distinguished names.

Referring to your statement appended below Dr. O'Connor's letter that I admitted in my evidence that these three distinguished medical friends were to send rejuvenation patients and share in the fees, such a statement was never made in court and I cannot see anything that was reported to convey such an impression though the sharing the fee statement in the report in the wrong order. Naturally only a fragment of my evidence was given. But I should like to make it clear that these three men knew nothing about the rejuvenation scheme.

I am, Sir, yours faithfully,

ANNE WALTON.

Radiant Health Institute, Wigmore-street, W.,
Nov. 24th, 1928.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

LOCAL GOVERNMENT BILL: MINISTER OF HEALTH'S EXPLANATION.

IN the House of Commons on Monday, Nov. 26th, Mr. CHAMBERLAIN, Minister of Health, in moving the second reading of the Local Government Bill, said that when they considered the magnitude of the changes which the Bill proposed, the variety of the interests which it affected, and its possible results upon the prosperity of the country, and indeed the social welfare of the whole community, he thought it must be reckoned among the greatest measures which had been presented to any Parliament for many years. It contained the final and completing stage of that great measure of rating reform, the earlier stages of which the House had already discussed in the Finance Bill and in the Rating and Apportionment Act of last session. Like most of our national institutions, local government had been a product of a process of evolution. Progress had been fitful and irregular. There had been moments of expansion and development, then there had been long intervals when it seemed to fall almost into a condition of somnolence. Everyone of these movements, if it was examined, would be found to have been a movement in the direction of the further expansion of the functions of local government and of their adaptation to the changing needs of the people, as the public conscience demanded that the standards of life should be raised, and as the community assumed further responsibility in respect of the health, the education, or the security of its members. If they looked back over the history of the last hundred years they saw standing out a succession of great measures which were, as it were, the crests which in turn they had surmounted as they had progressed upon the upward wave. Each of these measures represented the accumulated experience of the preceding years, and showed how it was necessary to adapt the conditions of local government to the altered conditions of the locality. After describing the scope and effect of the Poor Law Act of 1834 and later measures dealing with local government, including the Acts of 1888 and 1894, Mr. Chamberlain said that since those two Acts there had been no serious or radical attempt to reform local government. Yet they must consider what gigantic changes had taken place since then. The population of England and Wales had increased from 29,000,000 to 39,000,000, and its distribution had altered very considerably. New industries had sprung into existence, and older industries, some of them among those which seemed the most stable and permanent that we had in this country, withered and decayed. New services had been developed, and the expenditure of local authorities had gone up from about £36,000,000 in 1891 to nearly £250,000,000. The means of communication had been enormously facilitated by the development of the telephone. By the invention of the internal combustion engine, its perfection, and its adaptation to motor vehicles, the means of transit and transport had been so revolutionised that distances which in the old days took a whole day to travel might now be done in the course of an hour. All these things profoundly modified local conditions throughout the country, yet there were the same local authorities, the same areas practically as they were. It would be a miracle if it were not found that this stereotyping of the old conditions of government had not resulted in widespread friction, in widespread loss of efficiency, and inability to perform the functions which were given to them in such different circumstances. He could not imagine that there was any member of the House who had a greater belief in or admiration for our system of local government than he had. But it was just because he had seen for himself what local government could do, what he thought it ought to be; because he knew how many places there were in the country where it did not reach to the highest ideals, but where he would like to see them come up to it; because to his mind local government meant social reform, that he rejoiced that that day reform meant social reform, that he rejoiced that that day the opportunity had been given to him to bring forward this measure, which would, he believed, effect great reforms in bringing up the standard of the backward authorities somewhat nearer to what they ought to be.

Obsolete Points in Local Government.

During the four years that he had sat in the chair of the old presidents of the Local Government Board it had been borne in upon him with ever-increasing force that splendid as was our system of local government, it was to-day in many respects obsolete and out of date. Sitting there at the centre of things he could see the cracks and flaws in the machine, he could note how in one place the load had been growing and growing until it had become far greater than the shaft was originally designed to hoist. In another place

he could see remnants of old gears designed long ago which now only served to weaken and hamper the working of the more modern plant. It seemed to him that local government to-day cried aloud for reform, and in this measure they had a great scheme which was divided into various parts, some of which perhaps might seem to have little reference to one another, yet they were all parts of a whole, and in their turn each of them would do something to oil the wheels to ease the way, and to bring up the output of the machine both in quantity and quality to something far superior to what they were able to get to-day. The measure would have to be thoroughly and critically examined, but before they could examine the remedy it was necessary to diagnose the disease. He would like to lay before the House what seemed to him to be the main defects from which local government in this country was suffering to-day. These might be considered under five main heads. Firstly, the continued existence of the guardians among other local authorities with functions which overlapped one another, and presiding over areas the boundaries of which crossed the boundaries of the other local authorities, giving rise to confusion, to waste, and to inefficiency. Secondly, he would put the onerous charges which were fastened to-day upon county districts, and particularly the rural districts, in respect of the construction and maintenance of the modern types of roads which more and more were coming to be used for traffic which was of no direct benefit to the immediate locality, but which was passing through it. Thirdly, he would put the want of elasticity, the want of power readily and cheaply, to alter the boundaries of the districts themselves as their conditions change and the nature of the authority which administered them. Fourthly, he put the inequitable system of rates which had under modern conditions been subjecting our agriculture and industry to a slow process of strangulation; and fifthly, and lastly, he would point to the present chaotic conditions of the relations between national and local expenditure—the system under which national contributions to local needs too frequently meant that it gave in largest measure to those who had least need of it, while those who could not afford to maintain their own services got the smallest contribution from national resources.

Fluctuation and Overlapping.

The trouble with the poor-law was the same to-day as in 1834 in respect of the fact that the charges for poor-law, which fluctuated violently from time to time and which were largely beyond the control of the authorities which had to meet them, fell upon areas so small that the burden was apt to become suddenly and completely crushing. Of course, the inequalities would not be diminished, but increased by the proposals of the Government for de-rating, which would abstract from those authorities a large part of their rateable value and leave only a diminishing portion of it to bear any fluctuating charges which remained. That was not the only anomaly. Surely it was altogether indefensible that, say, in the area of a county borough the finance committee of the council, which ought to be the sole authority for the public finances of that borough, had to take account of an expenditure over which it had no control whatsoever—the expenditure of a body separately elected at elections at which only a very trifling proportion of the ratepayers could be induced to vote, and an expenditure which might, and often did, amount to 10 per cent. or more of the total expenditure of the town. Lastly, there was the question of overlapping. From time to time Parliament had entrusted the major local authorities with the responsibility for the prevention or the treatment of various diseases. There was tuberculosis, there was the charge of lunatics and mental defectives, there were the great maternity and child welfare services; and yet every one of those things had to be dealt with also by the guardians in the discharge of their duties, and they had this remarkable and paradoxical circumstance—that the question of whether a person should receive treatment at the hands of the county borough or the county council, or whether he should receive it under the poor-law from the guardians, depended not upon the nature of the disease or of his infirmities, but merely upon whether he was destitute or not. They might suppose from some of the criticisms that had been made in the country that the proposal to abolish the guardians and transfer their functions to councils of counties and county boroughs was his invention. He could not claim the authorship of any such idea, but he might say that he had inherited it. In 1888, when the Local Government Bill was under discussion, Mr. Joseph Chamberlain called the attention of the House to the omission from the Bill of any proposal to hand over to the county council the functions of the guardians. If Conservative governments had lent a more ready ear to the counsels of his forebear it would have saved his son a world of trouble. Both the Majority and Minority Report of the Poor Law Commission of 1909 concurred on this point, that the time had come to abolish the boards of guardians and to hand over their functions to the county councils and the county borough councils. The Maclean Committee in

1918 again unanimously concurred in this one recommendation. While everybody would feel a considerable amount of sympathy with the men and women who had given long years of devoted voluntary service to the work of boards of guardians, and who naturally would feel regret at seeing the boards broken up and the possibility that they might have to give up that work, he did not believe that from any responsible quarter in the House there would come any serious challenge to the proposal which they found in the first part of the Bill. The case did not depend merely upon the easing of the financial burdens, strong as it might be on that ground. It opened up a wide field for the improvement of our health services. The whole trend of practice in modern medicine and surgery was towards the treatment in many cases in institutions where there could be accumulated the specialised equipment and specialised skill which were not always available in private homes. When this Bill became law they would have a position in which there would be one single health authority in each area whose duty and function it would be to survey the whole institutional needs of that area. They would have at their disposal all the institutions which were now in the hands of the guardians; in many the accommodation was not fully occupied. They would have an opportunity of reclassifying their institutions, of closing such as were no longer suitable for modern requirements, of altering and adapting others, and using one for one purpose and another for another purpose. Even to-day there was a certain amount of classification attempted in many of the institutions of the guardians, particularly in the large areas, but he thought it must be clear that with the small opportunities that were to be found of each particular kind of case in any particular institution, it was quite impossible either to get the sort of classification that one wanted, or particularly, to bring to it that equipment and that specially skilled staff and nursing which were essential if one was to get the best results. He had taken out the particulars and the nature of the persons who happened to be in one particular institution on one night this month. He had chosen the institution at random, except that it was one in a rural area. This institution contained 7 acutely sick persons, 55 infirm and senile, 6 epileptics, 8 certified lunatics, 18 certified mental deficient, 9 uncertified mental deficient, 1 able-bodied man, and 3 healthy infants. No one could consider that that was a satisfactory state of things. It was clear that only a general review over comparatively large areas and a general readaptation of buildings would suffice if they were to get a satisfactory solution of that problem.

Incomplete Break-up of the Poor-law.

A certain amount of criticism had been directed to the point that the Government were not breaking up the poor-law. Under Clause 4 the county councils and county borough councils were given power to treat persons either under the poor-law or under a number of special Acts. If they adopted these special Acts, persons treated thereunder would be separated out and treated by other committees, according to the nature of their ailments. He was disposed to think that some day this should be made mandatory, but they were, at present up against two difficulties. In the first place, the local authorities were very jealous of their independence. There was a second and perhaps even greater difficulty—namely, that in many cases the councils had not sufficient institutions to be able to break up the poor-law. That, however, would come in the future, and no doubt this Bill would help it to come. How were these transferred functions to be dealt with? Of course, it was essential that the body which provided the money should retain financial control. At the same time he had been extremely anxious, and had taken some trouble to provide, that they should not so far as possible lose in any degree that local knowledge, that local interest and local experience that had been so valuable in the past, and in Clauses 3 to 7 there were provisions which showed how they were going to try to combine central financial control with the fullest possible use of that local knowledge. They had taken pains to insert in the Bill a provision that among the co-opted members of the public assistance committee must also be women. There could be no doubt that these committees would rank among the most important appointed by the council. The right hon. gentleman proceeded to describe the functions of the public assistance committees, and the subcommittees, which he said would be called guardians committees. He went on to say that Clause 13 provided for the recovery of expenses. The reason for inserting that clause was this. Under the existing law it was the duty of the guardians to recover either the whole or part of the cost of relief of any person who was maintained in their institutions. It was not the law that a local authority must do it, though some of it frequently did, and he thought that in the case of maternity homes they always did; but, obviously, if they were to transfer the functions of the guardians to the council they must not have a situation in which one person who happened to be destitute would have the cost of relief demanded from

him, while another person who was not destitute, but who went into an institution of his own accord, was to be let off. They must have one rule for both, and for that reason they had provided that in future the local authority would have the duty imposed upon it of recovering such part of the cost of maintenance in an institution as any inmate could afford. But they excepted from that provision the case of the infectious hospitals, where persons went for the good of the community; and that also included the case of the tuberculosis sanatorium.

Protection of the Maternity Services.

He noticed from the amendment paper that this was taken as involving some danger to the maternity services. At present he did not see how that could be the case. It was the general practice of local authorities to make charges for relief given in an institution, and seeing that the woman who had her confinement in an institution was relieved of the cost of doctor or midwife and that she had in most cases the maternity benefit secured to her, it was difficult to understand why she should not be asked to make some contribution to the cost of her maintenance in the institution. He had an open mind on the subject. He was anxious that nothing should be done that would in any way hamper or check the development of the maternity services, to which he attached the utmost importance, and if he could be convinced in committee that the provision here would have that effect, or that any amendment could usefully be inserted which would still further protect the maternity services, he would receive any such suggestion with respectful consideration. Referring to Part 2 of the Bill, which deals with registration services, Mr. Chamberlain said that these clauses were not consequential upon the great scheme of reform of the Government, and they might be omitted from the Bill without damaging the rest of it, but he thought that perhaps the House would feel that the registration services need not on this occasion be made a matter of controversy, and that perhaps they would be glad to lend their aid towards putting them on a basis which would be more satisfactory to them, and which would give them a better service in the future.

Clause 48 was designed to bring together education authorities and maternity and child welfare authorities. Obviously it was desirable that there should be continuity in the life of the child and where, as was the case at present, they had one authority which had the maternity and child welfare centre under its care, and other authorities which were education authorities who had no power to deal with maternity and child welfare, it was provided by the Bill that the maternity and child welfare services might be handed over to the authority which was also the education authority, so that continuous supervision might be exercised over the health of the child. Clause 50 provided in certain cases for the supervision of midwives; Clause 51 provided for a more satisfactory review of accommodation for infectious diseases in counties; and Clause 52 provided for power in London to delegate in future certain functions from the London County Council to the metropolitan borough councils.

Financial Provisions.

Proceeding to deal with the financial provisions of the Bill, Mr. Chamberlain asked what they were to put in the place of the present system of distributing national contributions? As far as he could see there were three ways open to them. The first was to take certain services right out of the purview of the local authorities, make them a national charge, and put them under national administration. That course was condemned by Mr. Lloyd George in 1912. To begin with it meant the apotheosis of bureaucracy; the creation of a new horde of officials from one end of the country to the other whose duties would overlap, and in some cases conflict with those of the local staffs. It would mean that it would be really impossible to separate the able-bodied unemployed from the ordinary person who was an applicant for poor relief, for one class constantly passed into the other. A plan of that kind would utterly fail to solve the present problem. It took no account of the relative wealth or poverty of different districts; it took no account of the differing needs of different services or of the differing costs of those services in different localities. The second course was to take the local expenditure as the basis for determining what should be received from the State. He turned that plan down at once because that was the very principle which, broadly speaking, was to be found in the other circumstances had brought about the necessitous of them. There remained only the plan upon which the local services should be distributed, not in accordance with what the local authorities spent, but with what were their needs. The needs, of course, must include their relative ability to pay, and he submitted that that was not merely the only equitable solution, but that it was the only one

which was going to find a practical remedy for the ills from which local government was suffering to-day. He had been very much astonished at suggestions made in quarters, whose sincerity he did not for one moment question, that a system of block grants was going to injure, or even sometimes it was said to starve the health services, and especially the maternity and child welfare services. If he thought for a moment that that would be so he never would allow it to go through, but he was convinced that those fears were utterly groundless. It was the greatest mistake in the world to think that a percentage system always resulted in achieving the ends which those who started it had in view. There were many cases to-day of localities which were comparatively wealthy, but which would not accept the bribe which was offered to them by the Government, because they did not want to put up their rates. There were other cases of localities which would gladly extend their services, but which could not, even with the aid of the 50 per cent. given by the Government, afford the money which was necessary. So again they got discrepancies between different towns and different localities which arose out of the percentage system. Here were some figures showing what was happening to-day. He should explain that leaving out of account three or four wealthy towns which had an exceptionally high expenditure upon this particular service, the average grant received by the authorities throughout the country from the Government in respect of their maternity and child welfare service was about 5d. per head of the population. He took one or two towns which were under the average, and which were therefore not getting the average maternity and child welfare service. First there was Oxford, a comparatively wealthy place with nearly £8 10s. rateable value per head of the population. Its maternity and child welfare grant to-day was 4d. What would it gain under the scheme? The gain in the first five-year period would be 20d. and the final gain when the full formula came into operation would be 31d. per head. He would take an entirely different case, that of Merthyr, whose rateable value was only £2 6s. per head. The maternity and child welfare grant was 4½d. The gain in the first quinquennium would be 73d. per head, and when the final formula was in operation it would be 108d. Dudley had a rateable value of £3 5s. per head; its maternity and child welfare grant was only 2-3d. per head; in the first quinquennium it would gain 65d. per head, and in the final operation of the scheme 124d. Tynemouth was a case where there was special need: the rateable value was £4 1s., and the maternity and child welfare grant was 3-8d. The gain in the first quinquennium would be 162d. and when the final scheme became fully operative, 200d. per head.

Adequacy of the Provision.

If the House would compare these figures of the gain per head with the amount that was being spent on maternity and child welfare service to-day, which on the average for the whole country was 5d. per head, was it not perfectly clear that the formula would give ample resources to every locality to deal with this service and to multiply it many times? There could not be any question about the adequacy of the amount of money for the service. After all, this was not an expensive service, and it did not take much money to produce considerable results. He had taken a good deal of trouble to protect it in the Bill. In Clause 75 it was provided that in the case of county districts voluntary associations would get, in addition to the population grant, an increased grant in order to enable them to carry on the service. Again, under Clause 83 the voluntary associations were protected, because the scheme which had to be prepared by the local authorities showing the amount of contribution which would be given to them had to receive the approval of the Minister, and he had the final say as to what the amount of the contribution might be. Then it might be said: "It is true you are going to give these ample resources to the local authorities, and they will have little excuse for neglecting this service, but unfortunately some local authorities are backward, they may be interested in other things, and they may not care to spend money upon this service which so many of us think so vital." He asked people who took that view to look at Clause 86, where they would see that the Minister had power, such as he had never had before, to take away the grant, or that portion of the grant which he might think right, from any local authority which was not keeping up this service to an adequate extent. That power would enable him to exercise far more influence to see that this service was kept up to the mark than he had ever had before. Here, again, if in the course of the discussions in Committee any good reason could be shown why the clause as drafted gave insufficient protection to local authorities, or rather to this particular service, he was ready to consider any amendments put forward. There was no service to which he personally attached more importance and in which he took a greater interest than maternity and child welfare, and he was not going to allow any consideration to interfere with the fullest possible development being afforded to it.

Concluding his speech, which occupied nearly two hours and a half in delivery, Mr. Chamberlain said: I venture now to make one prophecy. It is that this scheme of local government reform, although it may well be altered in its details and in its passage through this House, yet in its main outlines it will hold the field—(cheers)—and that in the fullness of time it will take its place on our Statute Book as a courageous, comprehensive, and a successful attempt to remove anomalies and injustices which have too long been allowed to impair and weaken the magnificent structure of our local government. (Loud prolonged cheers.)

Medical Members and the Local Government Bill.

The members of the Parliamentary Medical Committee, which includes members of all parties, met at the House of Commons on Tuesday, Nov. 27th, for the purpose of considering the effect of the Local Government Bill on medical questions and health services. The discussion was directed mainly to the question of how the medical services affected by the measure can best be maintained and developed. A number of points were raised, and the committee were not all agreed in their views. Eventually it was decided that it would be desirable to adjourn the meeting in order that members of the British Medical Association might attend. It is expected that another meeting, at which representatives of the British Medical Association will be present, will be held next week, when an effort will be made to go very thoroughly into the medical aspects of the Bill in preparation for the Committee stage.

OFFICES REGULATION BILL.

In the House of Commons on Wednesday, Nov. 21st, Miss WILKINSON asked leave to bring in a Bill to regulate offices and the employment of young persons therein. She said that the Bill was introduced by her last session and obtained the unanimous approval of the House. She appealed to the Home Secretary to use his influence in order that the Bill might be regarded as non-controversial, because anyone who read its extraordinarily moderate provisions, and who realised the great need which it was intended to meet, would feel that it was inconsistent with their duty as responsible members of the House to oppose the measure. She had been astonished at the number of letters which she had received from all over the country giving particulars of the conditions under which women in particular, but men also, had to work in offices. It was frequently forgotten that there was no protection, apart from the local sanitary by-laws, covering workers in offices. They were outside the factory legislation and the Shops Acts, and they unfortunately were a class who were not very highly organised. The grievances were getting steadily worse with the overcrowding in great cities, and the position was aggravated by women coming into offices which were never built to accommodate both sexes. The danger to health which came from bad ventilation was well known, and in a large number of offices, not only the older ones, but also those recently built, there was no ventilation, and the conditions towards the end of the day became very bad indeed. Among the letters she had received there was one which referred to one of the most modern office buildings in Regent-street. The office was underground, and artificial light was necessary all day. The worker in this case contracted anaemia, and had to be warned by her doctor that if she continued to work underground she was in danger of suffering from pernicious anaemia. The Bill was very moderate in its provisions; it took into account the fact that it was not possible to reconstruct all offices in the course of a year, and it gave wide powers to local authorities. It put the onus on the owner, who was often getting very high rents.

Leave was unanimously given to introduce the Bill, which was brought in and read a first time.

MOTOR VEHICLES INSURANCE.

Mr. WARDLAW-MILNE asked leave to introduce a Bill to make it obligatory upon owners of motor vehicles to be insured against third party risks.

Leave was unanimously given to introduce the Bill, which was brought in and read a first time.

HOUSE OF LORDS.

TUESDAY, NOV. 20TH.

WASHINGTON EIGHT HOURS CONVENTION.

The Earl of LYTTON moved—

That in the opinion of this House it is desirable (1) that the Government should inform the International Labour Office at Geneva of the precise points on which they desire a revision of the Washington Eight Hours Convention; and (2) that the Government should publish the text of a Draft Bill showing what modifications, if any, in the existing industrial agreements in this country would be required as a result of the ratification of

an International Eight Hours Convention in the amended form desired by the Government.

He said that he was not asking the Government to change their policy in any respect, or to ratify the Convention, but merely to define their policy. The situation was one in which everything was to be gained by complete frankness, and any vagueness or reticence could only cause suspicion and criticism. He had no doubt of the sincerity of the Minister of Labour and the Government in this matter, but they must not be surprised if their reticence and hesitation caused doubt in the minds of others.

Lord OLIVIER, on behalf of the Labour Opposition, supported the motion. He urged that the Government should make plain at once what their difficulties were in regard to the ratification of the Convention. Their silence on the subject created the greatest possible suspicion that pressure had been exercised from one side of the industrial world—namely, the National Federation of Employers' Organisations. The International Federation of Trade Unions, and the majority of the delegates from all the Governments represented at Geneva, were satisfied that the Convention was workable.

The Marquess of LONDONDERY (First Commissioner of Works) said the only point of honour was that the present Government, and every other Government of this country, must maintain and promote the application of the general principle of the eight-hour day or 48-hour week "so far as special circumstances permit." He could not believe that any general accusation of dereliction of duty on this head could be made against this country, or any of its Governments since the Treaty of Versailles was signed. The 48-hour week had long been an accepted principle in this country, and was the general basis on which our industrial employment rested. He was not sure that we could not claim to have been the first great industrial country to see its establishment. When, however, the Government came to examine the possibility of applying the provisions of the Draft Convention to British industry, with a view to ratification, it became clear that serious practical difficulties were involved; so serious, in fact, that the Government felt that they would not be justified in ratifying in face of them. The Governing Body of the International Labour Office had called for a report on all the Conventions adopted at Washington, and it was understood that the first report to be presented would be that on the Eight Hours Convention towards the close of this year. The Government had invariably made it clear whenever the subject of revision had been raised that they had no desire or intention to impair in any way the principle of the 48-hour week. Their desire was merely to render the Convention an instrument under which uniform practice and enforcement would be assured by removing its ambiguities and by making provision for various industrial practices which were in no way opposed to that principle. To publish at this stage the precise modifications which they proposed for their declared purpose would be altogether premature. The report on the working of the Convention was not yet to hand, and the Government could not bring forward its final proposals in advance of that report and of any international discussion thereon. It was quite out of the question to bring forward a Bill to give effect to the Government's proposals with regard to the Convention. Such a step would crystallise their proposals in such a way as to leave little, if any, scope for subsequent international negotiations, and would undoubtedly lay them open to the charge of attempting to force the hand of the General Conference and to dictate decisions to it in advance.

Viscount CECIL OF CHELWOOD said the Government could not expect agreement to be reached between the various parties concerned in this matter until they had made up their minds as to what it was they wanted.

The motion was negatived by 39 votes to 17—Government majority 22.

THURSDAY, NOV. 22ND.

PROTECTION OF ANIMALS (AMENDMENT) BILL.

Lord BANBURY OF SOUTHAM moved the second reading of the Protection of Animals (Amendment) Bill, which amends Section 3 of the Protection of Animals Act, 1911. That section provided:—

If the owner of any animal shall be guilty of cruelty within the meaning of this Act to the animal, the Court, upon his conviction thereof, may, if they think fit, in addition to any other punishment, deprive such person of the ownership of the animal, and may make such order as to the disposal of the animal as they think fit under the circumstances.

In the present Bill he proposed to add the further amendment:—

Further, if the owner of any dog shall be guilty of cruelty to that animal within the meaning of this Act, the Court upon the owner's conviction thereof, may, if they think fit, in addition to any other punishment, direct that such owner shall not thereafter for such time as they may direct, be granted any licence for keeping a dog or dogs, and a direction so given shall

be effectual to prevent such person so convicted from holding such licence.

The whole clause was permissive. It gave power to the magistrates to do certain things if they thought fit.

Lord DAWSON of PENN said while sympathising with the suggestion of Lord Banbury he thought that the difficulty of adding a provision like this was brought home when one realised that a number of terms were defined in Clause 15 of the original Act. For instance, the expression "domestic animal" was defined as well as the expressions "animal," and "captive animal," and "horse." Yet it was remarkable that there was no definition of "cruelty." He suggested that words should be added to define "cruelty" in view of the controversies that had been going on of late as to what was cruelty in connexion with experimentation on animals. A small paragraph might be added defining "cruelty" as "pain inflicted wantonly and heedlessly," which he believed was a definition supported by considerable authority.

Lord DESBOROUGH said while they must all feel great sympathy with Lord Banbury's object in introducing this Bill, there were certain features of it which would make it in the opinion of the Government almost impossible to carry it out. And even if it were carried out, it could be so easily evaded as to make the Bill practically inoperative. Licences were issued at 12,000 money order offices, and the Post Office were of opinion that it would be impossible to issue notices to all those offices of people who were disqualified by the magistrates from taking out a licence. It would also be easy for a disqualified person to get some relation to take out a licence if he wanted to keep a dog. The Government would not oppose the second reading of the Bill, but they could not hold out any hope that they would give it in its present form any great facilities in the future. If, however, it could be so amended as to make it feasible and practicable they would be glad to see it passed.

Lord BANBURY said he would consult with Lord Desborough and the Home Office as to methods by which the Bill could be amended. He had drawn the Bill so that they could not go into the question of cruelty, and had limited it to the enlargement of Section 3 of the Protection of Animals Act, 1911. He hoped that no attempt would be made to bring in other matters.

The Bill was read a second time.

PRESERVATION OF INFANT LIFE.

Lord DARLING moved the second reading of the Preservation of Infant Life Bill. He said that it was brought to his notice by one of His Majesty's judges early this year that there were a good many cases—far more than he himself would have thought likely—in which no punishment could be awarded to a person who had done a very cruel and wicked thing in killing a little child. If a child were fully born, and had a separate existence from the mother, to kill it would be murder. But if it had not yet got an absolutely separate existence, it might be killed and that was no offence at law. It did not come within the law which prohibited the procuring of abortion, because the child had gone beyond the stage at which that applied. There was no doubt that that gap in the law required to be filled. The subject had been carefully considered by a Select Committee to whom it had been referred after the previous Bill, which he introduced, received a second reading, and the present Bill was really their Bill and not his.

Lord ATKIN said the Bill in its present form was not a satisfactory piece of legislation. The gap in the criminal law which had been mentioned by Lord Darling undoubtedly existed, and had been recognised to exist by many generations of judges. To the logical mind of the criminal reformer it could not be said that the killing of a child which could not be proved to have had a separate existence was not a wrongful act, and that it might not properly be made an offence. But the practical effect of making it an offence would in his experience be very small indeed. Their Lordships would appreciate the circumstances of a trial for infanticide of a girl, who was nearly always an unmarried girl, and who, as happened in nearly every case, had given birth to a child for the first time. After a period of months of mental care, anxiety, and shame, such a girl was suddenly brought into labour with all the pangs of an unattended, uncared for, and possibly difficult labour in the case of a first delivery, and they might well understand that it was very difficult to persuade a jury that the acts of a woman in those circumstances were acts for which she ought to be held criminally responsible. It had been difficult enough in the past under the existing law to get convictions for infanticide. But when the girl was charged with an act done in the very course of delivery he thought it would be still more difficult. He did not believe that a single child life would be spared by this new provision.

A Social Defect.

But that was not really the reason why he complained of the Bill. There was a very grievous social defect in

It applied not merely to the mother but to third persons who by a wilful act, intending to destroy the life of a child did in fact cause its death. That applied to doctors and midwives—to doctors in particular—and it raised the momentous question as to what was the position of a doctor when he had to consider during delivery whether or not it was necessary to save the life of the mother or the life of the child. It would be seen that the scheme of the Bill was that such a doctor committed a criminal offence unless he proved, the onus being upon him, that he acted in good faith and that it was necessary to take the action he took in order to save the life of the mother. That would be an intolerable burden to throw upon the profession. He was much opposed to the practice in legislation of creating crimes and throwing the onus upon anyone of proving that he was innocent; it was a course which had been adopted far too freely, but never in such a serious case as this, where the maximum penalty was penal servitude for life. Doctors had been harried quite enough by litigation, and to add this burden to the cares of an ordinary practitioner was perfectly horrible. It was quite impossible. The onus put upon a doctor was bad enough; and it would be all the greater if the medical man who might have to consider this momentous question had to bear in his mind the question whether or not he might be charged by a disappointed parent, or by a malicious or mischief-making attendant, with this particular offence, when he would have to justify to a jury the question whether or not it was in fact necessary to lose the life of a child. For these reasons he thought that the Bill went very much further than was necessary. In so far as the Bill dealt with the offence of killing a child, the provision as to 28 weeks after conception seemed to be quite unnecessary, because such an act as that would, as he was advised, and as he understood, always be covered by the law as to procuring abortion. It was impossible in practice to kill the unborn child while still in the body of a mother without in fact procuring, and intending to procure, a miscarriage. While the Bill remained in its present form, in the interests of professional men, who specially required protection by their Lordships' House, it was, in his opinion, objectionable, and ought not to be passed.

LORD DAWSON associated himself with the arguments of Lord Atkin. They were bound to admit on the authority of Lord Darling that there was a gap in the law, and for the purposes of symmetry he conceived that there was an argument for filling that gap, but if one passed from the law to human considerations he suggested that it was a gap which their Lordships should not be too anxious to fill. The majority of these cases of infanticide to which the Bill referred were cases of unmarried mothers who had suffered for months under the stress of anxiety, culminating very often in difficult labour, when they could not be held as wholly responsible as ordinary mortals for their action, and he thought it was a very good thing if in many of these cases the law turned a blind eye to an offence of that character. Indeed, if one read the proceedings of the Law Courts one could detect that the judge trying the case was almost seeking for an opportunity to evade the conviction of these poor girls for felony which would mark them for the rest of their lives. In many cases what they needed was not legal conviction, but rather the hand of understanding and fellowship which would help them along the road again.

The Question of Responsibility of the Mother.

As far as his experience went, it could not honestly be said that they were fully responsible for their action at the time. If he put himself in the position of a professional man who had knowledge of an act of this kind taking place, he had no hesitation in saying, if he satisfied himself that the act had been performed under the stress of impulse and anxiety, he would consider it no part of his duty to divulge the fact to the powers that be; in fact, he would regard it as a matter in many instances, if it were done impulsively, as to which it was his duty to extend the advantages of professional privilege. Passing to the effect of the Bill on the medical profession, Lord Dawson pointed out the hardship that was inflicted on doctors and midwives, who were called upon to do their duty under considerable difficulties. This Bill, he said, threw upon them the onus of proving that they were not committing a crime. Apart from its injustice it would go far to inhibit and discourage them from doing their work without let or hindrance, and, from the point of view of fairness and justice to the doctor and the interests of the community, he emphatically urged their Lordships to reject the Bill.

EARL RUSSELL said if this were a crime which could be stopped by this Bill, and if it were a conscious crime which penalties would deter, there would be a great deal more to be said for the Bill going forward, but if it did go forward he felt that it would be advantageous to refer it again to the Select Committee to consider carefully all the circumstances, and particularly safeguards. To throw upon doctors and midwives the onus of proving that they were innocent was a very serious and a most undesirable thing.

The Government's Attitude.

THE LORD CHANCELLOR said that as this matter was eminently one of legal and criminal procedure, the House would like to hear from himself what attitude the Government took up in regard to it. When the original Bill came before their Lordships last summer he (Lord Hailsham) said that he doubted whether the cases were quite as frequent as Mr. Justice Talbot (who called attention to the gap in the law in a charge to the Grand Jury) seemed to think but that there was at present a position under which a child fully born could be killed with impunity either by its mother or by any third person, unless it could be proved that it had an independent circulation, did not seem to be a very satisfactory state in which to leave the criminal law. Assuming that there was a gap, then came the question as to whether this Bill satisfactorily closed it. It had been pointed out that there were two classes of persons, broad speaking, in regard to whom this Bill might be called in operation. First of all there was the mother of the child. Some of their Lordships had said that when an unmarried mother in the pangs of childbirth killed her child she was very often largely irresponsible, and hardly conscious of what she was doing. He did not think that any of the Lordships would dispute that proposition, but it applied not merely when she killed the child while it was in the act of being born, or before it had an independent circulation it also applied when she killed the child almost immediately after its birth, which was the common case of infanticide and which had been recognised as a crime by the law. He doubted it was true that when a crime of that kind was committed the circumstances under which it had been committed were matters properly to be taken into account, and under our modern system of criminal law were, he thought invariably taken into account in considering what steps should be taken in regard to the unfortunate woman. In many cases the courts had taken the view that in such a case it was not right that she should suffer any punishment but that some probation system should be brought into play under which she could be taken care of and shepherded into wiser and better ways. That, of course, would equal the case under this Bill should it become law. The same other classes of persons, the doctor and the midwife. With regard to that he agreed that it was most important that the position of such professional persons should be safeguarded. When the original Bill came before the Lordships' House attention was called to the very point which Lord Atkin and Lord Dawson had raised that afternoon, and it was partly on that account that the Bill was sent to a Select Committee which he noticed contained among its members Lord Dawson. Whether or not the exact phraseology of the Bill as it stood was sufficient safeguard that position was no doubt a matter which might well be carefully considered, either by a Select Committee or by their Lordships' House in committee, whichever might be more convenient. He (Lord Hailsham) was not sure that he quite agreed with Lord Atkin when he said that the burden was put upon the doctor of proving the necessity of taking life in order that he might escape from responsibility. What he had to prove was that he acted in good faith for the purpose of preserving the life of the mother, and although in fact he was mistaken in thinking that it was necessary for that purpose to kill the child, as he read the Bill the doctor would not be under any liability so long as he acted in the honest belief that the necessity existed. But that was a matter of phraseology, and eminently a committee point. It was obviously a point that should be made clear if there was any doubt about it, and since Lord Atkin took that point there was obviously a doubt which should be cleared away. He did not think, however, that that was a reason for rejecting the second reading altogether and leaving the gap in the law unclosed. In those circumstances he suggested that it would be reasonable to allow the Bill to have a second reading, and then to consider either by reference to a Select Committee or in committee of their Lordships' House.

LORD ATKIN said he would be quite content, as he supposed Lord Dawson would also be content, not to divide the House on the matter, being satisfied that the Bill should be considered in committee.

The Bill was read a second time.

HOUSE OF COMMONS.

WEDNESDAY, NOV. 21ST.

Women Medical Students.

MR. RHYS DAVIES asked the President of the Board of Education the number of women medical students who had entered for university training for each of the last five years in England, Scotland, and Wales respectively.—MR. A. J. SAMUEL (Financial Secretary to the Treasury) replied: I regret that the information in my possession does not

enable me to state the number of entries of women medical students. The returns made to the University Grants Committee show that the total numbers of full-time women medical students attending university institutions for the past five years have been as follows:—

—	1923-24.	1924-25.	1925-26.	1926-27.	1927-28.
England ..	1375	1197	1059	930	862
Wales ..	35	32	30	32	30
Scotland ..	610	431	313	274	254
Total ..	2020	1660	1402	1236	1146

Blind Persons Pensions.

Mr. ROBINSON asked the Secretary to the Treasury what amount had been disbursed in pensions under the Old Age Pensions Acts, 1908 to 1924, and the Blind Persons Act, since Jan. 4th, 1926, and the number of persons at present in receipt of pension under these Acts.—Mr. A. M. SAMUEL replied: The amount disbursed for pensions under the Old Age Pensions Acts, 1908-1924 (including pensions granted by virtue of the Act of 1925), and the Blind Persons Act, 1920, for the period Jan. 1st, 1926, to Sept. 30th, 1928, is approximately £86,600,000. The number of persons (including blind persons) receiving pensions under the Old Age Pensions Acts, 1908-1924, on the last Friday in September, 1928, was 1,320,106. This figure includes 330,568 pensions payable by virtue of the Widows', Orphans', and Old Age Contributory Pensions Act, 1925, to persons over the age of 70.

Covered Sanitary Refuse Carts.

Sir ROBERT THOMAS asked the Minister of Health what progress had recently been made in the adoption of covered sanitary refuse carts by local authorities; and whether his department had decided upon any particular design as being most generally suitable.—Sir KINGSLEY WOOD replied: A number of types of such vehicles are at present to be seen in the Public Health Exhibition in the Agricultural Hall and some of these are being extensively used by local authorities. The answer to the last part of the question is in the negative.

Gas Poisoning and Workman's Compensation.

Mr. STEPHEN MITCHELL asked the Home Secretary whether, seeing that gas poisoning was not included under the Workmen's Compensation Act, he would consider the question of having the Act amended so as to include gas poisoning as an industrial disease.—Sir W. JOYNSON-HICKS replied: I am not quite certain to what the hon. Member refers. There are various forms of poisoning by fumes of gas, which are already scheduled. If, however, the hon. Member is referring to poisoning from gases such as carbon monoxide, which takes effect very rapidly, the circumstances would, as far as I am aware, always be such as to constitute an injury by accident for which compensation can be claimed under the ordinary provisions of the Act.

Annual Increase in the Population.

Sir REGINALD NEVILLE asked the Home Secretary what was the estimated present annual increase of the population of England and Wales.—Mr. CHAMBERLAIN replied: According to the published official estimates, the average annual increase in population between the date of the 1921 census and mid-1927 is approximately 234,000 in England and Wales.

Post-raccinal Encephalitis.

Mr. GROVES asked the Minister of Health whether the five cases of post-raccinal encephalitis (four of which were fatal), referred to on page 115 of the Rolleston Committee's Report, were vaccinated with Government lymph.—Mr. CHAMBERLAIN replied: I am informed that four of the cases were vaccinated with Government lymph and one was not. The latter case, and three of the four former cases, were those in which death occurred.

THURSDAY, NOV. 22ND.

Children's Deaths from Small-pox and Chicken-pox.

Mr. CECIL WILSON asked the Minister of Health how many deaths of children under 15 had taken place in this country during the past ten years from small-pox and chicken-pox respectively.—Mr. CHAMBERLAIN replied: The numbers of deaths of children under 15 in England and Wales during the past ten years classified to small-pox and chicken-pox in the Registrar-General's Annual Reports and Statistical Reviews were 70 and 563 respectively.

Definition of Surgical Appliances.

Dr. VERNON DAVIES asked the Minister of Health, in view of his decision under the National Health Insurance Regulations that a spinal jacket required for the treatment

of tuberculosis of the spine was regarded as a splint, but that a spinal jacket required for the treatment of lateral curvature of the spine, which was often due to tuberculosis, was not a splint and, therefore, could not be supplied to insured persons, he would state his reasons for arriving at such a decision.—Mr. CHAMBERLAIN replied: The reason why a different view was taken with respect to the appliances in the particular cases in question is that I have to look not to the name given to an appliance but to the precise object which it is intended to serve. I have invited the Insurance Acts Committee of the British Medical Association to discuss with my department the difficulties of defining splints for the purposes of medical benefit, and I am sending my hon. friend a copy of the letter conveying the invitation which will indicate to him what are the points at issue.

Home Office and Codeine.

Colonel VAUGHAN-MORGAN asked the Home Secretary whether the alkaloid codeine had been added to the schedule under the Dangerous Drugs Act; if not, whether it was proposed to do so; and, if so, when that would be done.—Sir VIVIAN HENDERSON (Under Secretary to the Home Office) replied: The answer to both parts of the question is in the negative. Codeine is not regarded by most authorities as a habit-forming drug, and is not included in the International Conventions of The Hague and Geneva.

MONDAY, NOV. 26TH.

Morphine and Opium Alkaloids from India.

Lieut.-Colonel VAUGHAN-MORGAN asked the Under Secretary of State for India whether morphine and other alkaloids of opium were manufactured at the Government's factory at Ghazipur; if so, since when such manufacture had been carried on; what amount of morphine had been manufactured in each year since 1920; and what was the amount of revenue derived from its sale.—Earl WINTERTON replied: Various alkaloids of opium have been manufactured at the Ghazipur factory from waste products and contraband opium for many years, but it was not until about 1924 that they began to find a market in substantial quantities outside India. They are exported to the United Kingdom only, where their disposal for strictly medical and scientific purposes is governed by the stringent provisions of the Dangerous Drugs Act. The figures asked for in the last two parts of the question are given in the following statement:—

Season Nov. 1- Oct. 31.	Cata- mine hyd- chlor.	Mor- phine hyd- chlor.	Mor- phine acetate (A) and tar- trate (T)	Codeia (C) and narcoc- line (N)	Morphia crude (M) and codeia crude (C).	Revenue from sales.
	lb. oz.	lb. oz.	lb. oz.	lb. oz.	lb. oz.	Rupees.
1920-21	3 6	—	—	C 16 15	—	16,266
1921-22	0 10	34 6	—	—	—	9,123
1922-23	1 3	130 6	—	—	—	30,205

The Schick Test in London Area.

Mr. DAY asked the Minister of Health whether there were any methods of coöperation now in force between his Department and the various educational and administrative departments in the metropolitan area for the introduction of immunisation by means of the Schick test for the purpose of reducing the attack rate of diphtheria.—Mr. CHAMBERLAIN replied: Yes, Sir. Many of the metropolitan borough councils have undertaken, with the sanction of my Department, immunisation work of the kind indicated in the question. I understand that the London County Council do not directly participate in this work, but in their capacity as local education authority they assist, when requested, by the dissemination of information on this subject through the schools.

Coroners' Inquiries in India.

Mr. MANDY JONES asked the Under Secretary of State for India whether the system of inquiry by a coroner and jury into deaths due to other than natural causes which occurred in British India was in force throughout British India; and, if not, in which provinces, if any, the said

system of judicial inquiry was in force at the present time.—Earl WINTERTON replied: The system is in force only in the Presidency towns of Calcutta and Bombay.

New Admissions to Mental Hospitals.

Mr. CECIL WILSON asked the Minister of Health to state for each quarter during the last five years the number of new admissions to mental hospitals.—Mr. CHAMBERLAIN replied: New admissions to mental hospitals in England and Wales during the last five years have been as follow:—

Year.	To county and borough mental hospitals.	To all other institutions for the insane and to private single care.	Total.
1923	21,375	1,679	23,054
1924	19,704	1,599	21,303
1925	20,327	1,457	21,784
1926	20,466	1,458	21,924
1927	20,474	1,419	21,893

Figures are not available for each quarter.

The Radium Monopoly of Belgium.

Commander BELLAIRS asked the Under Secretary of State for Foreign Affairs, in view of the importance of radium to the health of nations, whether the Government would raise the question of the radium monopoly of Belgium at the League of Nations and protest against the great rise in price in spite of increased production.—Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) replied: The whole question of the radium requirements of this country in relation to present sources of supply is at present under consideration by a subcommittee of the Committee of Civil Research.

TUESDAY, NOV. 27TH.

Scottish Parish Councils and Local Government Bill.

Mr. THOMAS HENDERSON asked the Secretary of State for Scotland how many parish councils in Scotland had written to him protesting against the proposals contained in the Government's Local Government (Scotland) Bill, and how many in favour.—Sir JOHN GILMOUR replied: Twenty parish councils have written opposing the proposals generally, and 79 have written opposing the transfer of the powers of parish councils to county councils. Three parish councils have written in favour of the proposals.

Tests for Motor Drivers.

Mr. LOUIS SMITH asked the Minister of Transport whether, having regard to the ever-increasing number of motor accidents caused by inexperienced drivers, he would make it compulsory for a would-be driver of either a motor-car or motor-cycle to pass a suitable and thorough test before receiving a driving licence.—Colonel W. ASHLEY replied: I have no power to make applicants for driving licences submit to a driving test, and so far as I am aware there is no evidence to show that any substantial proportion of motor accidents are due to any want of capacity on the part of drivers such as would be disclosed by a test of this kind.

Medical Examination of Air Force Recruits.

Mr. LUNN asked the Secretary of State for Air how many men and boys offered themselves as recruits for the Royal Air Force during 1927; how many were accepted; and how many were rejected on medical grounds.—Sir S. HOARE replied: 8356 men presented themselves for recruitment, and 2171 boys sat for the education test during 1927. Of these 2453 men and 1030 boys were finally accepted, and 4042 men and 192 boys were rejected on medical grounds.

Births, Marriages, and Deaths.

BIRTHS.

- DREW.—On Nov. 23rd, at Greypoint, Worthing, to Mary, the wife of Dr. J. Grahame Drew—a daughter.
HUME.—On Nov. 23rd, at Southway, N.W. the wife of J. Basil Hume, M.S., F.R.C.S., of a daughter.
STUTTAFORD.—On Nov. 21st, at Horning, near Wroxham, Norwich, the wife of W. J. E. Stuttatford, M.C., M.R.C.S., L.R.C.P., of a son.

MARRIAGES.

- BISHOP—WILLIS.—On Nov. 22nd, at St. Mary's Church, Bromley, Kent, George Spencer Armitage Bishop, M.B., F.R.C.S.E., of Melton Mowbray, to Phyllis Marianne, youngest daughter of the late Mr. Walter Willis and Mrs. Willis, of Bromley, Kent.
CRAWFORD—GOETZE.—On Nov. 21st, at St. Martin-in-the-Fields, Edward Sydney Atkinson Crawford, B.A., M.B., B.Ch., B.A.O., T.C.D., to Marie Louise Pauline Goetze, M.R.C.S., L.R.C.P. Lond., M.B., B.S. Lond.

DEATHS.

- GOOD.—On Nov. 24th, at "Wayside," Pinhoe, Devon, Charles Walter Good, late of THE LANCET, aged 67.
HILL.—On Nov. 24th, suddenly, Dr. William Hill, M.D., B.Sc., of Weymouth-street, Portland-place.
JONES.—On Nov. 23rd, at Morley-road, Lewisham, Thomas Burnell Jones, M.R.C.S. Eng., L.R.C.P. Lond., aged 69.
RUSSELL.—On Nov. 22nd, at Langley-drive, Wanstead, John Hutchinson Russell, M.R.C.S., L.S.A. (late of Forest Gate), aged 69.
SMITH.—On Nov. 21st, at Balgonie House, Ryton-on-Tyne, James Wilkie Smith, M.D., C.M., D.Hy., aged 76.
N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical News.

UNIVERSITY OF OXFORD.—At a congregation held on Nov. 24th the degree of Doctor of Medicine was conferred on R. J. Brocklehurst, H. F. Turney, and D. G. T. Kerr Cross (in absentia).

Dr. Malcolm H. MacKeith has been appointed Dean of the Medical School.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on Nov. 24th the following degrees were conferred:—

M.D.—A. D. Whitelaw.

M.B. & B.Chir.—N. R. Barrett, H. S. Waters, P. R. Buckton.

UNIVERSITY OF LONDON.—At a meeting of the Senate held on Nov. 21st the degree of D.Sc. was conferred on Prof. F. G. Parsons (anthropology), University Professor of Anatomy, Mr. William Robson (biochemistry), Mrs. Norah Edkins (physiology), and Mr. J. W. Cox (psychology).

A course of five lectures on the rôle of Bacteria in Nature will be given by Dr. F. W. Twort at 4 p.m. on Dec. 3rd, 5th, 7th, 10th, and 12th, in the theatre of the Royal College of Surgeons, Lincoln's Inn-fields, London, W.C. Admission is free without ticket.

SOCIETY OF APOTHECARIES OF LONDON.—At a recent examination the following candidates were successful in the undermentioned subjects:—

Surgery.—J. Freud, Vienna and St. Bartholomew's Hospital; W. S. Ghai, Charing Cross Hospital; W. D. Glynn-Jones, Guy's Hospital; H. C. Johnson, Minnesota, U.S.A.; T. K. S. Lyle, King's College Hospital; A. Weeks, St. Bartholomew's Hospital.

Medicine.—J. Freud, Vienna and St. Bartholomew's Hospital; W. D. Glynn-Jones, Guy's Hospital; E. C. Gross, Guy's Hospital; M. H. Rashwan, Guy's Hospital; L. Wasef, Manchester.

Forensic Medicine.—W. D. Glynn-Jones, Guy's Hospital; D. F. Michael, St. Mary's Hospital.

Midwifery.—N. Datta, London Hospital; J. D. B. Games, St. Bartholomew's Hospital; E. C. Gross, Guy's Hospital; A. Liberis, St. Bartholomew's Hospital; T. K. S. Lyle, King's College Hospital; A. Weeks, St. Bartholomew's Hospital.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery: E. C. Gross, H. C. Johnson, T. K. S. Lyle, M. H. Rashwan, and L. Wasef.

Mr. H. W. Carson has left for America where he is delivering the Mutter lecture before the College of Physicians of Philadelphia.

A HOSPITAL JEWEL CASKET.—A committee of ladies is collecting jewellery to form a casket to be presented to the Queen when she opens the extensions of the Elizabeth Garrett Anderson Hospital next spring. It is hoped to endow a bed by the sale of the jewels.

Messrs. Edward Arnold and Co. announce the early appearance of a second edition of "Diseases of Children," the first edition of which was edited by Sir Archibald Garrod, Dr. Hugh Thursfield, and the late Dr. F. E. Batten. The new volume will be edited by Dr. Thursfield in collaboration with Dr. Donald Patterson.

PAY-BEDS AT SUNDERLAND.—As the result of enlargements two wards in Sunderland Royal Infirmary are being altered and modernised for the reception of 22 paying patients. For an experimental period of a year the board of management have fixed the fees for maintenance and nursing at three guineas weekly in the open wards and five guineas in the two-bed wards.

Obituary.

SIR HECTOR CLARE CAMERON, C.B.E., M.D.,
F.R.F.P.S. GLASG., LL.D.

THE death of Sir Hector Cameron on Nov. 22nd closes a long and useful career as surgeon, teacher, and administrator. Appointed to full charge of the surgical wards of the Royal Infirmary at Glasgow as long ago as 1875, he was professor of clinical surgery in the University during the first ten years of this century, and continued to do strenuous work for hospitals and medical education until comparatively lately.

The son of Duncan Cameron, sugar planter of Demarara, Hector Cameron was born in British Guiana

SIR HECTOR CAMERON.

Photograph by James Glasgow.

55 years ago, and was sent as a boy to Scotland where for some time he lived in the household of Norman Macleod, the younger, then parish minister of Dalkeith. Thence he went to the Madras College at St. Andrews and to Edinburgh University where he began the study of medicine. Most of his medical instruction, however, was gained at Glasgow, and in his year of graduation, 1866, he was appointed house surgeon to Joseph Lister at the Royal Infirmary. This appointment naturally had a great influence on Cameron's opinions and ambitions, and it was also the beginning of a friendship between the surgical pioneer and his young assistant. When Lister left Glasgow in 1869 Cameron found himself one of the chief exponents of antiseptic surgery in Glasgow, and as the new creed was beginning to get approval—though by no means always understanding—the path of hospital promotion and consulting practice lay wide open before him. So capable a man was not slow to grasp his opportunity. He became a Fellow of the Faculty of Physicians and Surgeons in 1870 and received appointments at the Glasgow Eye Infirmary and Lock Hospital. Then at the early age of 32 he was given full charge of the Royal Infirmary's surgical wards, an appointment which he held with distinction during the next six years. When he resigned in 1881 it was to go as surgeon to the Western Infirmary, at the same time joining the staff of the newly established Royal Hospital for Sick Children. To these institutions he brought a true appreciation of what Lister's system meant, and he taught it as practised by Lister himself. His services were thus of immense advantage to the Glasgow medical school. "Before his appointment," writes Sir George Beatson, "antiseptic surgery at the Western Infirmary was carried on in a very haphazard and lax manner, the surgeons being formerly on the staff of the Royal Infirmary, in Lister's day, when, as we all know, the surgeons

regarded Lister's views and work with scepticism and sided with the managers, who were ever actively hostile to it and opposed it. But Cameron soon made his influence felt. As a teacher it was well known that he won the confidence and good opinion of his students, being a clear and lucid lecturer. In his operative work he followed his teacher Lister in not aiming at brilliancy, but brought to his work a careful judgment and attention to detail that made him a very successful surgeon. Consequently he soon won an outside reputation and had a very large practice."

As Lister's disciple and missionary Cameron was in a position to spread his teaching far and wide through graduates of the Glasgow medical school, and in the process he won for himself the reputation, as a colleague puts it, of being "to many generations a beloved master, and to the people of the West of Scotland a tower of strength and confidence." President successively of the Glasgow Medico-Chirurgical Society, the Pathological and Clinical Society, and, in 1897, of the Faculty of Physicians and Surgeons, he also became a power in the University. When George Buchanan resigned the chair of clinical surgery in 1900 the Court appointed Cameron to succeed him without even advertising for other candidates. Thus he reached professorial rank at the comparatively late age of 57.

The fact that teaching and private practice always made great demands on his time probably explains why his contributions to surgical literature were fewer than might have been wished, considering his comprehensive experience and powers of lucid and accurate expression. As long ago as 1876, however, he contributed *Illustrations of Antiseptic Surgery* to our columns, and in later years he several times had occasion to write illuminating reviews of the progress of operative technique, besides recording a certain number of clinical observations. In 1907 appeared his "Evolution of Wound Treatment in the Last Forty Years," which may be regarded as a surgical confession of faith. He was one of a small committee which in 1909 was responsible for the issue of the "Collected Papers of Lord Lister," the other members being Watson Cheyne, Rickman Godlee, C. J. Martin, and Dawson Williams, and only last year, in connexion with the centenary of his old chief, he gave accounts of his personal reminiscences to appreciative audiences. Cameron's memory was indeed always one of his greatest assets. "His exceptional and almost extraordinary power of remembering what appealed to his imagination," writes Mr. A. E. Maylard, "stored his brain with an amount of knowledge that found a ready outlet in his work, so that he never lacked that which enabled him in operating to surmount the difficulties he might encounter. . . . None in later life can have failed, however short the acquaintance, to have come under the spell, indeed gift, of telling a good story. Here, also, his exceptional power of memorising anything he may have heard or read in prose or poetry seems to have served him well." His great capacity for attracting strangers and keeping friends was used to the full. He was universally esteemed and liked, and he stood very high in the opinion of his medical brethren and of the community at large, which admired and trusted him.

Retiring in 1910 at the age of 67 from his University chair, it might have been thought that he would enjoy a leisured existence. With the war, however, there came new chances of service, and he became Red Cross Commissioner for Western Scotland with supervision of nearly 3000 beds. In this work his sagacity and outstanding tact were highly valued by his colleagues, and good use was again made of these qualities when in 1921 he was appointed by the General Medical Council to supervise examinations conducted by medical schools throughout Great Britain and Ireland. Representative of the Royal Faculty of Physicians and Surgeons on the Council from 1888 to 1903, he was already fully familiar with its educational work, and despite his 78 years was

system of judicial inquiry was in force at the present time.—Earl WINTERTON replied: The system is in force only in the Presidency towns of Calcutta and Bombay.

New Admissions to Mental Hospitals.

Mr. CECIL WILSON asked the Minister of Health to state for each quarter during the last five years the number of new admissions to mental hospitals.—Mr. CHAMBERLAIN replied: New admissions to mental hospitals in England and Wales during the last five years have been as follow:—

Year.	To county and borough mental hospitals.	To all other institutions for the insane and to private single care.	Total.
1923	21,375	1,679	23,054
1924	19,704	1,599	21,303
1925	20,327	1,457	21,784
1926	20,466	1,458	21,924
1927	20,474	1,419	21,893

Figures are not available for each quarter.

The Radium Monopoly of Belgium.

Commander BELLAIRS asked the Under Secretary of State for Foreign Affairs, in view of the importance of radium to the health of nations, whether the Government would raise the question of the radium monopoly of Belgium at the League of Nations and protest against the great rise in price in spite of increased production.—Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) replied: The whole question of the radium requirements of this country in relation to present sources of supply is at present under consideration by a subcommittee of the Committee of Civil Research.

TUESDAY, NOV. 27TH.

Scottish Parish Councils and Local Government Bill.

Mr. THOMAS HENDERSON asked the Secretary of State for Scotland how many parish councils in Scotland had written to him protesting against the proposals contained in the Government's Local Government (Scotland) Bill, and how many in favour.—Sir JOHN GILMOUR replied: Twenty parish councils have written opposing the proposals generally, and 79 have written opposing the transfer of the powers of parish councils to county councils. Three parish councils have written in favour of the proposals.

Tests for Motor Drivers.

Mr. LOUIS SMITH asked the Minister of Transport whether, having regard to the ever-increasing number of motor accidents caused by inexperienced drivers, he would make it compulsory for a would-be driver of either a motor-car or motor-cycle to pass a suitable and thorough test before receiving a driving licence.—Colonel W. ASHLEY replied: I have no power to make applicants for driving licences submit to a driving test, and so far as I am aware there is no evidence to show that any substantial proportion of motor accidents are due to any want of capacity on the part of drivers such as would be disclosed by a test of this kind.

Medical Examination of Air Force Recruits.

Mr. LUNN asked the Secretary of State for Air how many men and boys offered themselves as recruits for the Royal Air Force during 1927; how many were accepted; and how many were rejected on medical grounds.—Sir S. HOARE replied: 8356 men presented themselves for recruitment, and 2171 boys sat for the education test during 1927. Of these 2453 men and 1030 boys were finally accepted, and 4042 men and 192 boys were rejected on medical grounds.

Births, Marriages, and Deaths.

STUTTAFFORD.—On Nov. 21st, at Horning, near Wroxham, Norwich, the wife of W. J. E. Stuttaford, M.C., M.R.C.S., L.R.C.P., of a son.

MARRIAGES.

BISHOP—WILLIS.—On Nov. 22nd, at St. Mary's Church, Bromley, Kent, George Spencer Armitage Bishop, M.B., F.R.C.S.E., of Melton Mowbray, to Phyllis Marianne, youngest daughter of the late Mr. Walter Willis and Mrs. Willis, of Bromley, Kent.
CRAWFORD—GOETZE.—On Nov. 21st, at St. Martin-in-the-Fields, Edward Sydney Atkinson Crawford, B.A., M.B., B.Ch., B.A.O., T.C.D., to Marie Louise Pauline Goetze, M.R.C.S., L.R.C.P. Lond., M.B., B.S. Lond.

DEATHS.

GOOD.—On Nov. 24th, at "Wayside," Pinhoe, Devon, Charles Walter Good, late of THE LANCET, aged 67.
HILL.—On Nov. 24th, suddenly, Dr. William Hill, M.D., B.Sc., of Weymouth-street, Portland-place.
JONES.—On Nov. 23rd, at Morley-road, Lewisham, Thomas Burnell Jones, M.R.C.S. Eng., L.R.C.P. Lond., aged 69.
RUSSELL.—On Nov. 22nd, at Langley-drive, Wanstead, John Hutchinson Russell, M.R.C.S., L.S.A. (late of Forest Gate), aged 69.
SMITH.—On Nov. 21st, at Balgonie House, Ryton-on-Tyne, James Wilkie Smith, M.D., C.M., D.Hy., aged 76.
N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical News.

UNIVERSITY OF OXFORD.—At a congregation held on Nov. 24th the degree of Doctor of Medicine was conferred on R. J. Brocklehurst, H. F. Turney, and D. G. T. Kerr Cross (in absentia).

Dr. Malcolm H. MacKeith has been appointed Dean of the Medical School.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on Nov. 24th the following degrees were conferred:—

M.D.—A. D. Whitelaw.

M.B. & B.Chir.—N. R. Barrett, H. S. Waters, P. R. Buckton.

UNIVERSITY OF LONDON.—At a meeting of the Senate held on Nov. 21st the degree of D.Sc. was conferred on Prof. F. G. Parsons (anthropology), University Professor of Anatomy, Mr. William Robson (biochemistry), Mrs. Norah Edkins (physiology), and Mr. J. W. Cox (psychology).

A course of five lectures on the Role of Bacteria in Nature will be given by Dr. F. W. Twort at 4 p.m. on Dec. 3rd, 5th, 7th, 10th, and 12th, in the theatre of the Royal College of Surgeons, Lincoln's Inn-fields, London, W.C. Admission is free without ticket.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examination the following candidates were successful in the undermentioned subjects:—

Surgery.—J. Freud, Vienna and St. Bartholomew's Ho W. S. Ghai, Charing Cross Hospital; W. D. Glynn, Guy's Hospital; H. C. Johnson, Minnesota, T. K. S. Lyle, King's College Hospital; A. W. Bartholomew's Hospital.

Medicine.—J. Freud, Vienna and St. Bartholomew's W. D. Glynn-Jones, Guy's Hospital; E. C. Hospital; M. H. Rashwan, Guy's Hospital Manchester.

Forensic Medicine.—W. D. Glynn-Jones, G. D. F. Michael, St. Mary's Hospital.

Midwifery.—N. Datta, London Hospital; St. Bartholomew's Hospital; E. C. Gro A. Liberis, St. Bartholomew's Hospital; King's College Hospital; A. Weeks Hospital.

The Diploma of the Society was given to candidates, entitling them to practise midwifery: E. C. Gross, H. C. J. M. H. Rashwan, and L. Wasel.

Mr. H. W. Carson has left delivering the Mutter lecture of Philadelphia.

He was a popular teacher, and his readiness to share in all work of healing and amelioration of symptoms won him the confidence of general practitioners, who alone know the amount of unostentatious work that Dr. Hill performed without any thought of remuneration.

Dr. Hill was a great reader, but was also keen on outdoor pursuits. In his leisure times he was never more happy than when engaged in yachting and sea-fishing either in the West of England or at Ramsgate, where he was a popular member of the Royal Temple Yacht Club. He was happily active to the end, having seen his last patient only 20 minutes before his death. He will be greatly missed, not only by those who knew him intimately but by all to whom his genial presence was familiar.

An old friend writes:—"Forty-one years ago I first met William Hill when he appeared in the library of Epsom College to preside over the matriculation examination of the London University. Three years later I encountered him in the dissecting room of St. Mary's Hospital Medical School, where he occupied the position of senior of a handsome trio of demonstrators—Hill, Roughton, and Cagney. Hill's control of the department was perfect. Anatomy, however, did not long retain him; before long he had become aural surgeon to St. Mary's Hospital, and for years has been recognised as one of the foremost specialists in that branch of surgery. His tragic and unexpected death will be mourned by a host of good friends. The secret of his popularity was in his qualities of unfailing good temper, urbanity, a natural kindness of disposition, and a keen sense of humour. His hospitality was enjoyed by many, and he was a charming host. He was greatly in request as an after-dinner speaker, for he had a pungent humour coupled with a naive address which never failed to amuse. His excellent memory made it easy for him to exploit the foibles and fancies of his listeners, but his wit was never unkind, and his great delight was to get back as good as he gave. One of the qualities that so greatly endeared him to his friends was his constant endeavour to help those younger than himself. His hand was ever at the service of those who exhibited a keen desire to learn. His prominence as a Freemason was a tribute to his sterling qualities. He was one of the founders of the Sancta Maria Lodge, became master in 1910, and in that capacity was a great success. He had a large share in the prosperity of the William Harvey Royal Arch Chapter, and his services were recognised some years ago by promotion to the rank of Past Grand Deacon of England. To the end he was one of the strongest supporters of the Sancta Maria Lodge, and many of those present a fortnight ago will long remember that their last meeting with him was under such happy auspices."

William Hill married Flora Hastings, daughter of David Robert Comyn, to whom our sincere sympathy is extended. A memorial service held at St. Mary's Hospital on Nov. 28th was large attended by friends, colleagues, and former pupils.

SYDNEY JAMES CLEGG, O.B.E., M.D. MANCH., D.P.H.

WE regret to announce the death on Nov. 23rd of Dr. Sydney Clegg, whereby a useful life spent in the public health service has been cut short at the early age of 40. Dr. Clegg's home was at Swinton, near Manchester, and he studied medicine at the Victoria University, qualifying in 1909. He was possessed of a splendid physique and distinguished himself at this time in many branches of sport, being captain of the University first eleven for both football and cricket. After holding an appointment at the Crumpsall Infirmary, and a term in private practice, he joined the staff of the Newcastle-upon-Tyne Health Department, rising gradually from a resident medical officer at the Infectious Diseases Hospital to the position of deputy medical officer of health.

During the late war he was amongst the earliest volunteers for overseas service, joining a fighting battalion as medical officer; from this he was taken

to organise and command one of the first sanitary sections. His wide knowledge and experience of sanitation brought him rapid promotion, until by the end of the war he was D.A.D.M.S., 3rd Army Corps. He was awarded the O.B.E. (Military) and the Médaille d'honneur des épidémies (en argent). He was the means of introducing, among other things, methods of dealing with refuse and for the control of

DR. S. J. CLEGG.

milk, which were adopted over the whole of the Western Front. At the end of the war he returned to Newcastle, where, writes Prof. H. Kerr, he was extraordinarily popular with all sections of the community, and was held in the highest esteem by members of the City Council. In 1923 he obtained the appointment of medical officer of health for Durban, Natal, for which post he received a unique testimonial signed by no less than eight ex-lord-mayors of Newcastle-upon-Tyne, while he was accorded a special farewell banquet by members of the City Council and other friends. He remained for five years in Durban where he strove hard for the improvement of the local preventive machinery—and with considerable success, as was attested on all sides. The position, was, however, uncongenial to one of his temperament, and his feeling of ineffectiveness, together with the rigours of the climate, exacted heavy toll from his health. He returned to England last September and took up residence at Rhos-on-Sea; here he was struck down by lobar pneumonia, which ended fatally in a few days, his powers of resistance not yet having recovered their normal tone.

"Clegg's passing," Prof. Kerr continues, "removes a striking figure from preventive medicine. His wide sympathies and broad outlook endeared him to all with whom he came in contact and created for him a very large number of friends." Great sympathy will be felt with his widow.

HERTFORD COUNTY HOSPITAL.—This institution is to be enlarged at a cost of £35,000. The number of beds will then be 131, and the domestic accommodation will be much improved. The kitchens are officially described as "right down in the basement and pitch dark." This hospital has nine times been enlarged or rebuilt since its establishment in 1833.

MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH.—The office-bearers of this Society for 1928-29 will be:—President: Dr. A. Logan Turner. Vice-Presidents: Dr. R. A. Fleming, Dr. C. E. Douglas, and Mr. J. W. Dowden. Councillors: Prof. William Russell, Dr. Frederick Porter, Dr. David Huxley, Mr. J. J. M. Shaw, Dr. Charles McNeil, Dr. Andrew Ritchie, Dr. Murray Wood, and Mr. J. W. Struthers. Treasurer: Dr. Maer Taylor. Secretaries: Dr. Alexander Goodall and Mr. A. Pirie Watson. Editor of Transactions: Dr. Fergus Hewat.

able to travel all over the country in the course of his duties.

In 1924 Cameron was called upon to unveil the statue of Lord Lister in Kelvingrove Park, and two years later himself received a testimonial to the affection and friendship of his old pupils and fellow citizens. Two portraits of him were painted by public subscription, one of them being presented to the University of Glasgow and the other to himself. This was the last of a long series of honours, including a knighthood conferred in 1900, the C.B.E. in recognition of his war services, and the honorary degree of Doctor of Laws granted in 1910 and 1911 by the Universities of St. Andrews and Glasgow.

Mr. Henry Rutherford says of his old teacher and colleague: "It is over 40 years since I first met him in 1882, when I was a student in his clinic at the Western Infirmary, Glasgow. I remember well how I was impressed by his quiet, courteous manner, in relation both to patients and students. On the rare occasions when examination post mortem showed

him to have been wrong in opinion or procedure, he told the class frankly and explained as far as might be the cause of error... His interests were not confined to professional matters. He was widely read and remembered what he had read, and this was only one instance of his excellent memory; it concerned men and things heard or seen. He was as observant on the hillside, the links, or beside the river as he was among his patients. He loved tracking the birds and identifying the various callers. He was a good shot; a friend and colleague once said of him, with something of a complaint, that he was 'as siccar with his gun as he was with his knife.' He leaves a happy memory, gracious and inspiring."

Sir Hector Cameron married in 1872 Frances, daughter of William Hamilton Macdonald. She died seven years later, leaving him with four children, three of whom survive. Of his sons the elder is Colonel Donald Cameron, R.A.S.C., and the younger is Dr. Hector Charles Cameron, physician to Guy's Hospital.

GEORGE WILLIAM HILL, M.D. LOND., F.R.F.P.S. GLASC.

THE death of Dr. William Hill, consulting surgeon for diseases of the ear, nose, and throat to St. Mary's Hospital, occurred with startling suddenness on Saturday, Nov. 24th, while he was still actively engaged in the pursuit of his profession.

Born in 1858, William Hill was the son of George Hill, of Tregassick, Cornwall, and had even as a boy the sociable and attractive personality which was to become so well known in professional circles. He was educated at King's College, London, and studied for a brief period at St. George's Hospital before entering St. Mary's with the Senior Entrance

Science Scholarship in 1879. He had a brilliant career as a student, taking prizes in physiology, medicine, and surgery, and the scholarship in pathology. He was made demonstrator of histology and biology even before qualification, and during this period, in 1881, took the B.Sc. London with honours. He then became junior demonstrator of anatomy and assistant pathologist, qualifying

DR. WILLIAM HILL.

L.S.A. in 1884, and gaining honours in the Final M.B. London in 1885. For two years after qualifying Dr. Hill practised medicine in Cornwall, but in 1886 he returned to London and took up throat and ear work, becoming registrar and pathologist at the Central London Throat and Ear Hospital. At the same time he renewed his active connexion with the Anatomical Department at St. Mary's, holding the post of demonstrator and assistant lecturer in anatomy at the Medical School from 1887 to 1894. His versatility at this period of his career was remarkable, since besides working as clinical assistant in the

aural department of the hospital, he acted also as lecturer in botany at University College from 1886 to 1890, in which year he found time to take his M.D. In 1894 he was appointed aural surgeon to St. Mary's, and when, in 1908, the ear and throat departments were amalgamated they were placed under Dr. Hill's charge. He remained surgeon to the newly formed ear, nose, and throat department at St. Mary's for 11 years, and on his retirement in 1919 was elected consulting surgeon.

Dr. Hill was especially interested in the study of endoscopic methods for the examination of the air and food passages, and at the time of his death still held the post of endoscopic surgeon (for diseases of the gullet) at the Metropolitan Ear and Nose Hospital. The practical instruments he has devised in this connexion, as the outcome of his researches, will ensure his lasting fame. Soon after the introduction of the direct method of examining the upper air and food passages, he became a pioneer in the application of the method to the œsophagus, and of the introduction by this means of radium into malignant tumours of this region. He showed great ingenuity in designing and adapting instruments for the treatment of these cases, and devised the "Hill's tube" for the intubation of malignant œsophageal strictures. In the course of his investigations on œsophageal disease the possibility of developing direct gastroscopic examination occurred to him. Such examinations had been attempted by various observers without much success, but the publication in 1912 of Hill's book on Gastroscopy and the Œsophago-Gastroscope, renewed interest in the subject. The gastroscope associated with Hill's name can be passed into the stomach with safety, and gives an excellent view of the interior of the organ.

Dr. William Hill was a prominent member of medical societies. He presided over the Oto-rhino-laryngological section of the B.M.A. in 1921, and over the Harveian Society. He was a vice-president of the old Laryngological Society of London, and in 1914 President of the Laryngological Section of the Royal Society of Medicine, being until his death an active member of the latter body, and a regular attendant at its meetings. He was a member of the committee of the London and Counties Medical Protection Society. As recently as July of this year he read a paper on the treatment of certain forms of deafness by radium, at the annual meeting of the B.M.A. at Cardiff.

In his own home William Hill exhibited the same geniality as in his public life, and was always ready to offer to relatives or friends, whether in sickness or in health, entertainment or professional advice, according to the need of the moment. His charm of manner attached him to all who came in contact with him socially and professionally.

peak year of 1924 there has been a progressive decline in the reported incidence of this disease. Among the attempts to deal with the administrative problems of post-encephalitis lethargica, the "encephalitis unit" at Winchmore Hill continues to fulfil a very useful function in the case of juvenile patients mainly from the metropolitan area, and owing to the diminishing demands of London cases, extra-metropolitan applications for admission have been considered and a certain number met.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Albemarle-street, W.

THURSDAY, Dec. 6th.—1.30 P.M.—The following papers will be read: A. E. Boycott, F.R.S., C. Diver, S. Hardy, and F. M. Turner: The Inheritance of Sinistrality in *Limnaea peregrina*. R. H. Burne, F.R.S.: A System of "Fine" Vessels associated with the Lymphatics in the Cod (*Gadus Morhua*). E. Hindle: Further Observations on Chinese Kala-azar. The following papers will be read in title only: Eric Ponder: Haemolysis by Brilliant Green and Serum. (Communicated by Sir E. Sharper Schafer, F.R.S.) A. V. Hill, F.R.S., Grace Eccleston, and P. Eggleston: The Coefficient of the Diffusion of Lactic Acid through Muscle. C. H. Best, K. Furusawa, and J. H. Ridout: The Respiratory Quotient of the Excess Metabolism of Exercise. (Communicated by A. V. Hill, F.R.S.) A. V. Hill, F.R.S., and W. Hartree: The Energy Liberated by an Isolated Muscle during the Performance of Work. A. V. Hill, F.R.S.: The Diffusion of Oxygen and Lactic Acid through Tissues. (Parts I., II., III., and IV.) D. Keilin, F.R.S.: Cytochrome and Respiratory Enzymes. F. R. Miller and N. B. Laughton: Myograms yielded by Faradic Stimulation of the Cerebellar Nuclei. (Communicated by A. B. Macallum, F.R.S.) D. Burk: The Free Energy of Glucose-Lactic Acid Breakdown in Muscle. (Communicated by A. V. Hill, F.R.S.) F. C. Smith: The Ultra-violet Absorption Spectra of certain Aromatic Amino-acids and of the Serum Proteins. (Communicated by C. Lovatt Evans, F.R.S.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Dec. 4th.—8.30 P.M.—ORTHOPAEDICS. A discussion on the Stiff and Painful Shoulder. Opener: Mr. George Perkins. Other speakers: Mr. McCrae Aitken, Mr. Alan Todd, Dr. Alexander Mercer, Mr. J. R. Lee, Mr. B. Whitechurch Howell, Dr. Brailford, and others. Meeting at 8.30 P.M. at St. M. H. G. Vaccine Garrod: T. H. G. B. Hume: T. Jockes and E. H. K. G. Cantt: C. J. Dark Ground Unit: Illumination.

WEDNESDAY.—1.30 P.M.—SURGERY (at Guy's Hospital). Operations. Demonstration of cases.

THURSDAY.—8.15 P.M.—TROPICAL DISEASES. Paper: Dr. H. Harold Scott and Dr. H. B. Day: Clinical and Pathological Correlation in Typhoid and Allied Diseases.

FRIDAY.—10.30 A.M.—OTOLOGY. (Cases at 9.30 A.M.). Discussion on Meningitis. Papers will be read by: Mr. G. J. Jenkins, Mr. T. B. Layton: An Otitic Meningism; and Mr. E. D. Davis: The Morbid Anatomy, Prevention, and Early Diagnosis of Otitic Meningitis. Mr. L. Watson Williams will take part in the discussion. Cases and specimens will be shown by Sir James Dundas-Grant, Mr. Bernstein (introduced by Mr. Archer Ryland), Mr. W. M. Mellison, Mr. Norman Barnett, and others. 5 P.M.—LARYNGOLOGY. (Cases at 4 P.M.) Demonstration of lamp for local application of ultra-violet rays by Dr. A. Eldinow. Cases and specimens will be shown by the President, Sir James Dundas-Grant, and Mr. Victor Negus. 8.30 P.M.—ANÆSTHETICS. Paper: Mr. Stanley Rowbotham: Preliminary Medication in Anæsthetics.

FRIDAY, Dec. 7th.—3.30 P.M., Dr. Barnes: Medical Cases.

MINISTRY OF HEALTH. ANNUAL REPORT OF THE CHIEF MEDICAL OFFICER, 1927.

(Continued from p. 941.)

CANCER.

THE steady annual increase in the recorded mortality-rate of cancer, which has been noted for many years past, continues, and in 1927 the total number of deaths attributed to cancer was 54,078, giving a rate per million persons living of 1376. Sir George Newman holds that steady increase of this rate during the last 80 years does not of itself demonstrate an increase in the incidence or mortality of cancer. We cannot accurately assess the improvement in pathological knowledge, the advance in technical equipment and skill, the change in the age-incidence of the population, the newer bases of classification and improvement in diagnosis and methods of treatment. To many minds it seems a highly important question whether cancer is or is not increasing. The fundamental idea underlying the question presumably is that if it could be shown that some other change affecting the population as a whole, which might conceivably be a causal factor in disease, had taken place coincidentally with the recorded increased mortality of cancer there would be a *prima facie* case for inquiring whether there was a connexion between the two events. To regard the matter from this point of view seems to make the tacit assumption that all forms of cancer are due to a single cause. Most of the evidence suggests that this point of view may be misleading, and that the disease is in essence a purely local one, dependent upon some local change in the organ affected. Sir George Newman holds, therefore, that a more valuable line of inquiry than that of attempting to ascertain the measure of an over-all increased mortality which

leading usually to skin cancer, as in tar, paraffin, and briquette workers, chimney sweeps, mule spinners, aniline dye workers, X ray workers and the like; (2) the treatment of a few conditions, usually the result of chronic irritation or inflammation, recognised as precursors of cancer at certain sites—e.g., in the lip, tongue, and uterus. Pending the acquisition of further knowledge on causation which may open up methods of prevention, the two chief modes of attack open to those concerned with the disease are (a) the reduction of mortality by effective treatment, and (b) the relief of suffering. Along these two lines the main efforts of the Committee have hitherto been directed.

The main investigations constituting the Committee's programme for the immediate future are:—

(1) Radiological treatment. Technical investigations of its value and administrative inquiries as to how best it can be fostered.

(2) Investigation of certain sites—e.g., skin, mouth, and tongue—with the object of analysing present knowledge and in the hope at a later stage of securing further information on causation and prevention.

(3) Inquiry into the conditions under which patients with inoperable or recurrent cancer pass the remainder of their lives—e.g., the proportion admitted to infirmaries, that remaining at home, treatment available and received, &c.

(4) The accuracy of death certification in cancer and the proportion of cases receiving effective treatment.

(5) Completion of analysis of data already collected respecting cancer of the breast.

The projected inquiry into cancer of certain sites such as the skin, the lip, and tongue is largely based on considerations set out earlier in the report—viz., localisation to areas which either undergo specific forms of irritation, as in the occupational cancers of the skin, or in which cancer is known to follow certain pathological conditions, as in the lip and tongue, which are visible and therefore more readily capable of clinical investigation. Another advantage of this inquiry is its comparability with the experimentally induced cancer in animals. In

*Encephalitis lethargica ..	—	—	—	—	—	541	890	1470	454	1025	5039	2635	2267	1615

* Made notifiable Jan. 1st, 1919.

could be correlated with some supposedly aetiological factor would be to confine attention to a single organ at a time, to try to ascertain whether in the case of that organ an increase or decrease is taking place, and, if so, whether any reason for the change can be discovered.

Comparison of the actual number of deaths which were certified during 1926 and the years previous to it as due to cancer of the different organs, and the proportionate frequency with which the deaths were distributed among the organs, shows that though the differences between one organ and another in any given year are considerable, the frequency with which any given organ is affected in adjacent years is of roughly the same order. For this reason the Departmental Committee on Cancer of the Ministry, which has now been in existence for five years, decided to begin by investigating the disease as it affects particular organs. The sites selected for first investigation were the breast, uterus, and rectum. The results of the investigations hitherto undertaken have been published in the Series of Reports on Public Health and Medical Subjects, obtainable from H.M. Stationery Office.

Prevention.

The prime object of a central health authority is, however, prevention of the disease. With present knowledge prevention, as distinct from early and effective treatment, is limited to (1) avoidance of irritation arising out of a few occupational risks

this group of cancers, skin, lip, and tongue, are to be found those in which our knowledge of causation has some pretensions to accuracy and it is reasonable to suppose that, with adequate facilities for detailed investigation, this knowledge can be increased.

INFECTIOUS DISEASES OF THE NERVOUS SYSTEM.

The only diseases of the nervous system which any public health measures can directly influence are those which are to some extent infectious, such as poliomyelitis, polio-encephalitis, cerebro-spinal fever, and encephalitis lethargica. The incidence of these diseases, as shown by notification returns, 1914-27 inclusive, is shown in the table.

These figures show that the reported prevalence of encephalitis lethargica and acute poliomyelitis was considerably less than that during 1926; the 1927 figures for poliomyelitis are still higher than usual, but this is due to the fact that a considerable number of cases belonging to the season of 1926 occurred in the early part of 1926. The figures for polio-encephalitis and cerebro-spinal fever are also above the average for recent years.

In 1926 encephalitis lethargica and acute poliomyelitis were most prevalent in the first and third quarters of the year respectively, while cerebro-spinal fever, as usual, was chiefly prevalent in the winter months. It is satisfactory to note that the number of notified cases of encephalitis lethargica is 652 less than in the previous year and that since the

peak year of 1924 there has been a progressive decline in the reported incidence of this disease. Among the attempts to deal with the administrative problems of post-encephalitis lethargica, the "encephalitis unit" at Winchmore Hill continues to fulfil a very useful function in the case of juvenile patients mainly from the metropolitan area, and owing to the diminishing demands of London cases, extra-metropolitan applications for admission have been considered and a certain number met.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Albemarle-street, W.
THURSDAY, Dec. 6th.—4.30 P.M.—The following papers will be read: A. E. Boycott, F.R.S., C. Diver, S. Hardy, and F. M. Turner: The Inheritance of Sinistrality in *Limnaea pereana*. R. H. Burne, F.R.S.: A System of "Fine" Vessels associated with the Lymphatics in the Cod (*Gadus Morrhua*). E. Hindle: Further Observations on Chinese Kala-azar. The following papers will be read in title only: Eric Ponder: Hemolysis by Brilliant Green and Serum. (Communicated by Sir E. Sharpey Schafer, F.R.S.) A. V. Hill, F.R.S., Grace Eccleston, and P. Eccleston: The Coefficient of the Diffusion of Lactic Acid through Muscle. C. H. Best, K. Furusawa, and J. H. Eidout: The Respiratory Quotient of the Excess Metabolism of Exercise. (Communicated by A. V. Hill, F.R.S.) A. V. Hill, F.R.S., and W. Hartree: The Energy Liberated by an Isolated Muscle during the Performance of Work. A. V. Hill, F.R.S.: The Diffusion of Oxygen and Lactic Acid through Tissues. (Parts I, II, III, and IV.) D. Kellin, F.R.S.: Cytochrome and Respiratory Enzymes. F. R. Miller and N. B. Laughton: Myograms yielded by Faradic Stimulation of the Cerebellar Nuclei. (Communicated by A. B. Macallum, F.R.S.) D. Burk: The Free Energy of Glucose-Lactic Acid Breakdown in Muscle. (Communicated by A. V. Hill, F.R.S.) F. C. Smith: The Ultra-violet Absorption Spectra of certain Aromatic Amino-acids and of the Serum Proteins. (Communicated by C. Lovatt Evans, F.R.S.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
TUESDAY, Dec. 4th.—8.30 P.M.—ORTHOPEDICS. A discussion on the Stiff and Painful Shoulder. Opener: Mr. George Perkins. Other speakers: Mr. McCrae Aitken, Mr. Alan Todd, Dr. Alexander Mercer, Mr. J. R. Lee, Mr. B. Whitechurch Howell, Dr. Brailford, and others. 5 P.M., PATHOLOGY. Laboratory meetings at St. Bartholomew's Hospital. Demonstrations: M. H. Gordon and W. J. Tullock: Antibodies to Vaccine Virus. E. A. Carmichael: Microglia. L. P. Garrod: ... W. Shaw: ... B. Hume: Unusual Forms of Hydronephrosis. T. Joekes and F. H. K. Green: Infectious Anemia in Rats. Surgical Unit: Pathological Specimens. R. G. Cantl: Cinematograph of Tissue Cultures Under Dark Ground Illumination.
WEDNESDAY.—4.30 P.M., SURGERY (at Guy's Hospital). Operations. Demonstration of cases.
THURSDAY.—8.15 P.M., TROPICAL DISEASES. Paper: Dr. H. Harold Scott and Dr. H. B. Day: Clinical and Pathological Correlation in Typhoid and Allied Diseases.
FRIDAY.—10.30 A.M., OTOTOLOGY. (Cases at 9.30 A.M.). Discussion on Meningitis. Papers will be read by: Mr. G. J. Jenkins, Mr. T. B. Layton: An Otitic Meningitis; and Mr. E. D. Davis: The Morbid Anatomy, Prevention, and Early Diagnosis of Otitic Meningitis. Mr. E. Watson Williams will take part in the discussion. Cases and specimens will be shown by Sir James Dundas-Grant, Mr. Bernstein (introduced by Mr. Archer Ryland), Mr. W. M. Mollison, Mr. Norman Barrett, and others. 5 P.M., LARYNGOLOGY. (Cases at 4 P.M.). Demonstration of lamp for local application of ultra-violet rays by Dr. A. Eddow. Cases and specimens will be shown by the President, Sir James Dundas-Grant, and Mr. Victor Nogus. 5.50 P.M., ANESTHETICS. Paper: Mr. Stanley Rowbotham: Preliminary Medication in Anesthetics.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

YELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, Dec. 3rd, to SATURDAY, Dec. 8th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Mon., at 5 P.M., Lecture by Dr. G. A. Sutherland: Some Cardiac Problems in Childhood.
WELLSIDE MUSEUM OF MEDICAL SCIENCE, 33, Gordon-

street, W.C. Wed., at 4 P.M., demonstration by Mr. Herbert Paterson on Cancer.—ALL SAINTS' HOSPITAL, Vauxhall Bridge-road, S.W. Wed., at 2.30 P.M., clinical demonstration in Urology by Messrs. Attwater, Coyte, Loughnane, and Levy.—HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C. Thurs., at 10 A.M., clinical demonstration by Dr. Robert Hutchison. The above are free.—HOSPITAL FOR DISEASES OF THE SKIN, Blackfriars-road, S.E. Special course, afternoons only.—THE INFANTS HOSPITAL, Vincent-square, S.W. Afternoon special course.—WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck-street, W. At 5 P.M., lecture demonstrations daily. Further particulars from the Secretary.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Dec. 3rd.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Simmonds: Surgical Out-patients.
TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases (demonstration). 2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose and Ear Department.
WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards. 4.30 P.M., Dr. Carter Braine: X Ray Therapy.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Ironside: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Department.
FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.
SATURDAY.—9 A.M., Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.

Daily 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anaesthetic Course.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, Monday, Dec. 3rd.—4.15 P.M., Dr. Charles Sinker: Diphtheria. Last lecture on the History of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Dec. 3rd.—2.30 to 5 P.M.: Medical, Surgical, and Gynecological Clinics. Operations.
TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.
WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.
THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.
FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Dec. 4th.—5 P.M., Dr. W. Griffith: Eczema (1). THURSDAY.—5 P.M. Eczema (2).

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Dec. 6th.—4 P.M., Dr. Schlesinger: Congenital Syphilis.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Dec. 7th.—4 P.M., Mr. Archer Ryland: Oesophagoscopy.

ST. PAUL'S HOSPITAL POST-GRADUATE COURSE, Endell-street, W.C.

THURSDAY, Dec. 6th.—4.30 P.M., Dr. David Thomson: Common Infection of the Genito-urinary Tracts.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

WEDNESDAY, Dec. 5th.—4 P.M., Dr. R. Fortescue Fox: Rheumatism in Relation to Industry (with lantern illustrations).

CHADWICK PUBLIC LECTURES.

TUESDAY, Dec. 4th.—6.30 P.M. (at the Royal Sanitary Institute, 99, Buckingham Palace-road). Mr. H. C. Adams, M.Inst.C.E.: The Drainage of Basements and Low-lying Areas and the Prevention of Damp.

INSTITUTE OF HYGIENE, 28, Portland-place, W.

WEDNESDAY, Dec. 5th.—3.30 P.M., Dr. R. King Brown: The Use and Abuse of Artificial Sunlight.

NATIONAL INSTITUTE FOR THE DEAF, 2, Bloomsbury-street, W.C.

TUESDAY, Dec. 4th.—8 P.M. (at 40, Chandos-street, W.). Mr. C. M. R. Balbi, A.M.I.E.E.: The Wonders of Hearing. Chairman: Lord Charnwood.

EAST LONDON HOSPITAL FOR CHILDREN, Glams-road, Shadwell, E.

WEDNESDAY, Dec. 5th.—4 P.M., Cases illustrating the respiratory affections of Children will be shown.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Dec. 4th.—4.15 P.M., Mr. P. R. Wrigley: Oesophageal Obstruction.

FRIDAY.—4.15 P.M., Prof. H. S. Rapier: Obesity.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

FRIDAY, Dec. 5th.—5.30 P.M., Dr. Barnes: Medical Cases.

Appointments.

MACLEOD, C. B., M.B., Ch.B. Glasg., has been appointed one of the Medical Referees under the Workmen's Compensation Act for the Island of Lewis.

PEARSON, T., M.B., Ch.B. Manch., D.P.H., Deputy Medical Officer of Health for Gateshead.

Vacancies.

For further information refer to the advertisement columns.

Albert Dock Hospital, Connaught-road, E.—Res. M.O. At rate of £110.

Barnsley, Beckett Hospital.—Jun. H.S. At rate of £140.

Barnstaple, North Devon Infirmary.—H.S. At rate of £150.

Bedford, Bedfordshire Education Committee.—School Dentist. £500.

Belfast, Joint Nursing and Midwives' Council for Northern Ireland.—Examiners.

Bihar, India, Jharra Mining Settlement.—Chief M.O. 1200 Rs. a month.

... Hospital.—Asst. Ophth. Surgeon. £50.

... Hospital.—Cas. O. At rate of £250.

... Hospital.—Hon. Ophth. Surg.

... Hospital and Sanatorium.—

... Hospital and Sanatorium.—Asst. Res.

... M.O. 1200.

Cambridge, Addenbrooke's Hospital.—H.S. At rate of £130.

Cottingham, E. Yorks, Tuberculosis Sanatorium.—Res. M.O. £485.

Derby, Derbyshire Royal Infirmary.—Two H.S.'s. Each at £150.

Dorset Mental Hospital, Herrison, Dorchester.—Jun. Asst. M.O. £300.

Dreadnought Hospital, Greenwich, S.E.—Asst. Pathologist to

London School of Clin. Med. £350. Med. Supt. £300. Also

H.P. and H.S. Each at rate of £110.

Dumfries, Crichton Royal Mental Hospital.—Clin. Path. £400.

East Ham Memorial Hospital, Shrewsbury-road, E.—Res. M.O.

and Res. H.P., and Cas. O. At rate of £150 and £100

respectively.

Hampstead General and North-West London Hospital, Haverstock-

Hill, N.W.—H.S. Also H.P. Each at rate of £100.

Haywards Heath, Sussex, King Edward VII. Memorial, Eliot

theatist.

... Hospital.—Asst. Res. M.O. £250.

Great Ormond-street, W.C.—Surgeon.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Kirbymoorside, Yorkshire Children's Orthopaedic Hospital.—H.S. £150.

Liverpool, Fazakerley Sanatorium.—Asst. Res. M.O. £250.

Liverpool, Hahnemann Hospital, Hope-street.—Stipendiary M.O.

At rate of £125. Res. M.O. At rate of £100. Also Clin. Asst.

London Lock Hospital, 91, Dean-street, W.—H.S. At rate of £200.

Luton Borough.—Asst. M.O.H., &c. £600.

Manchester, Ancoats Hospital.—Orthopaedic Registrar. Also

Med. Registrar. £100.

Manchester, Salford Royal Hospital.—Res. Surg. O. £200.

H.P.'s. and H.S.'s. Also Cas. H.S. Each at rate of £125.

Metropolitan Hospital, Kingsland-road, E.—Asst. Surg. Also

Res. Cas. O. At rate of £100.

National Hospital, Queen-square, W.C.—H.P. £150.

Prince of Wales's General Hospital, Tottenham, N.—Hon. Anæ-

sthetist. £20. Also Hon. Clin. Assts.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—

District Res. M.O. Also Asst. Res. M.O. Each at rate of £80.

Royal Dental Hospital, 32, Leicester-square, W.C.—Hon.

Anæsthetist.

Royal Northern Hospital, Holloway, N.—H.S. At rate of £70.

St. Leonard's-on-Sea, Buchanan Hospital.—Jun. H.S. £100.

St. Luke's Infant Welfare Centre, Peckham, S.E.—Medical

Woman required.

St. Marylebone Hospital, W.—Visiting Consulting Neurologist.

£100.

St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden,

W.C.—Clin. Assts.

Salisbury, General Infirmary.—Pathologist. £1000.

Shanghai Municipal Public Health Dept.—Asst. Radiologist.

Also Asst. Pathologist. 700 and 650 taels per month

respectively.

Sheffield University.—Sen. Demonstratorship in Anatomy. £400.

... County M.O.H. £1100.

... H.S. £170.

... S.W.—Geoffrey Duveen

... Oto-Rhino-Laryngology. £450.

At rate of £150.

York County Hospital.—H.S. £150.

The Chief Inspector of Factories announces vacant appointments

for Certifying Factory Surgeons at Walton-on-the-Naze

(Essex), and Horsmonden (Kent).

COVENTRY AND WARWICKSHIRE HOSPITAL.—The governors of this hospital have decided to purchase for £65,000 the adjoining Coventry City Infectious Diseases Hospital. The acquisition will enable the accommodation to be increased ultimately by 102 beds, an administrative block, and quarters for 32 nurses.

THE KING'S ILLNESS.

OFFICIAL BULLETINS.

THE following is the text of the official bulletins which have been issued during the King's illness by Sir Stanley Hewett and Lord Dawson of Penn:—

WEDNESDAY, NOV. 21ST. 8 P.M.

His Majesty the King is suffering from a cold with some fever and is remaining in bed.

THURSDAY, NOV. 22ND. 8 P.M.

His Majesty has passed a restless day owing to persistence of the fever. There is some congestion of one lung.

FRIDAY, NOV. 23RD. 11.45 A.M.

The King passed a restless night, the temperature remaining at 101°. There is a slight extension of the mischief in the lung, but His Majesty's strength is maintained.

8 P.M. The King has had a quieter day; the temperature is lower and there is no further extension of mischief in the lung.

SATURDAY, NOV. 24TH. 11.15 A.M.

The King has passed a fair night, and the improvement noted last evening is maintained. The pleurisy which commonly accompanies this type of congestion of the lung continues to be a prominent feature.

7.45 P.M. The King has passed a quiet day. The condition of the lung is unchanged.

SUNDAY, NOV. 25TH. 7.45 P.M.

The King has had a disturbed day due to an increase in the fever. The strength is maintained.

MONDAY, NOV. 26TH. 10 A.M.

The King has passed a restless night. The variability in the fever and the spread of the pleurisy must be expected at this stage of the illness.

8.30 P.M. His Majesty the King has not had a comfortable day. The temperature is now 101.6°, but the pleurisy has not extended further, and the strength is maintained.

TUESDAY, NOV. 27TH. 11 A.M.

His Majesty the King has had a more restful night, and the temperature is somewhat lower. Conditions are otherwise unchanged.

8.30 P.M. The King has passed a less disturbed day; the temperature is somewhat lower than at the corresponding hour last night; the strength is maintained.

WEDNESDAY, NOV. 28TH. 10 A.M.

The King has passed a quieter night. The temperature and general condition remain as before.

2 P.M. (in a letter to the Cabinet). The King is suffering from inflammation (congestion) of the right lung with extensive plastic pleurisy on the right side, which as you know is a painful condition. Such an infection must from its nature be serious. In all illnesses of this character there must be anxiety, which will continue for the present, but I am happy to say that the King passed a quieter night, that the condition of the lung shows some improvement, and that his strength is maintained. So far, then, the illness is being controlled, its force lessened, its symptoms alleviated, and I hope its duration will be curtailed.

8.30 P.M. The King has passed a fair day, with some sleep. Otherwise conditions are unchanged.

REBUILDING OF MIDDLESEX HOSPITAL.—It is expected that shortly before Christmas it will be possible to remove the scaffolding from the new west wing, six storeys high, though this part of the building may not be ready for occupation until next autumn. There will be 12 large wards in this wing, the ground floor of which will be occupied by secretarial and other administrative offices.

Bradshaw Lecture

ON

AXIAL ROTATION, PURPOSEFUL
AND PATHOLOGICAL.Delivered before the Royal College of Surgeons
of England on Nov. 8th, 1928,

By C. H. FAGGE, M.S. LOND.,

MEMBER OF THE COUNCIL OF THE COLLEGE; SURGEON TO
GUY'S HOSPITAL.*Of the Dog called Turnspete in Latine
Turnspeter.*

There is comprehended, under the Curres of the courst kind, a certaine dog in kitchen-service excellent. For when any meat is to be roasted, they go into a wheel, which they turning round about with the weight of their bodies, so diligently look to their business, that no draught or fault can do the fire more cunningly. Whom the popular sort hereupon call Turnspets, being the last of all those which wee have first mentioned.

*The History of Fire-ferred Beests.
TOPSELL 1567*

THE necessities of existence must have forced upon man from his earliest days the consideration of mechanical problems. In what form rotation was first appreciated by him we do not know, but palæolithic man has handed down to us the bow drill which besides enabling him to perforate stones, also provided him with one of the earliest methods of kindling fire. With truth Aristotle, who died in the year 322 B.C., described man as a "tool-making animal," for the finding of tools of an earlier period at any spot is now accepted by archaeologists as conclusive evidence of former human habitation. The pump drill (Fig. 1) is of later date and is attributed by Seerig to Hippocrates, 400 B.C., although Flinders Petrie says that it was not known before Roman days. This implement well exemplifies the action of rotation due to a couple and shows how the power expended as the cord unwinds is recovered as it rewinds itself in the reverse direction round the spindle of the drill. But not until Archimedes, about 200 B.C., laid down the principles of helical motion was it realised that not only translation but also spiral or helical motion of a nut could be brought about by rotation of a screw. Here we perceive the discovery of a fundamental principle of mechanics, and from it may be traced the birth of much of the machinery of the present day. To surgeons the interest lies not in the helical motion of the nut upon the screw but in the axial rotation of the screw upon the nut, as shown in the mechanism of the drill designed by the Syracusan scientist over 2000 years ago and still part of our professional outfit. Yet in spite of the discovery of Archimedes, mechanics made comparatively slow progress, both theoretically and practically, until the Newtonian age, when in 1686, less than 250 years ago, Isaac Newton set down his laws of motion.

I am told that my title, Axial Rotation, has no exact mechanical sense, but it is well understood in surgical pathology as meaning the rotation of a body about its central vertical axis. When we reduce this motion to mechanical terms, we find that rotation of this kind is brought about either by the action of a couple consisting of two forces, equal, parallel and opposite, or of one force and a reaction which is a resistance acting in an opposite direction. The twisting action of the moment of this couple can be represented by the following formula, in which ϕ indicates the angle of rotation, a the radius of wire or pedicle and n its modulus of rigidity, or specific capacity for resistance to torsion.

The formula and diagram are introduced only because they help us to a broad conception of the magnitude of the forces required to form a couple so as to cause rotation of a living pedunculated

mass. Clearly the magnitude of C is in ratio to the value of a , l , and n ; while the greater the value of R the less will be that of W . Whereas n , the modulus of rigidity of a suspending wire, is a constant

$$2WR = C = \frac{\pi l^2 a^4 n}{360 l} \phi$$

n = modulus of rigidity of wire
 l = length of wire in centimetres
 a = radius of wire
 ϕ = angle of twist in degrees
 C = moment of couple of forces
 R = radius of drum
 W = weight or force

Mr. T. W. Adams, demonstrator of physics at Guy's, has carried out some experiments with the object of finding out the factors which influence torsion of a pedicle. By running water through a twisted rubber tube, representing the artery of a pedicle, he finds that forces are set up which tend to oppose the twisting couple; this may be considered as equivalent to increasing n . If this conclusion can be applied to living tissues it would suggest that the arterial pressure in a living pedicle opposes the forces which twist it, so that n , its modulus of rigidity, is raised until it reaches a limiting value and rotation ceases. If this be accepted, arterial pressure is a natural protection against torsion. This conclusion is in accordance with another common experiment; when watering a lawn with a long hosepipe one is constantly reminded that the force of the water in the pipe tends to undo twists.

PURPOSEFUL ROTATION.

Therapeutic Rotation.

As a surgical operation axial rotation is recognised in two distinct and widely different fields. Our modern ideas on arterial torsion for hæmorrhage are due to Amussat,¹ even though his experiments on living animals and on man a hundred years ago—at the time critically discussed and apparently regarded as original by his peers, Lisfranc and Larrey—had been forestalled by the Pneumatists: for to Heliodorus, Archigenes, and Antyllus, who in the first century were in surgery the equals of Celsus in medicine, torsion of bleeding vessels was a recognised method, apparently even then of some antiquity, as they made no claim to originality in its use. Prof. A. Chauffard, of Paris, has been kind enough to supply me with a précis of a thesis by Magon² in which Amussat's work and that of his successors is reviewed; he recalls that torsion of arteries was employed by MacCormac at Sedan in over a hundred cases. Castration by torsion is employed in veterinary surgery, chiefly in birds and small domestic animals, in order to render a male bird or animal used for the table more tender for the epicure. By some this method is preferred to ligature which, according to Hobday,³ is liable to be followed by tetanus. The method is known as *bistourmage* and may be employed in two ways; in this country the cord is clamped and the testis then twisted off, but alternatively the testis and cord may be isolated and the testis rotated

of known value, we know nothing of the modulus of rigidity of a living pedicle. If the pedicle is thin the forces required to produce a given twist may be small, but a thick pedicle like the body of the uterus must have a

very high resistance to torsion, as this is proportionate to the fourth power of its radius. Further, even if n is low during the first half-turn of a living pedicle, it will increase enormously when the twists are becoming tight.

four or five times and left to atrophy. Prof. A. Chauveau,⁴ in his classical observations on pathology written in 1873, used this common operation to illustrate his views. He states that if the arteries of the twisted cord were injected after death the coloured material did not pass beyond the twists. Tissue necrosis followed by atrophy of the testis resulted, and this Chauveau regarded as an example of tissue death unassociated with putrefaction. Yet, as Roche⁵ points out, "in pathological torsion, redness and oedema result from inflammation due to the damaged testicle, which acts as a foreign body." This difference may be explained on the hypothesis put forward by Bonney⁶ in a paper contrasting the effects of "occluding and suboccluding ligatures" on the tissues distal to them. He argues that the former produce a condition of white infarction—the aseptic death of Chauveau—whereas red infarction results when the circulation is incompletely cut off by a suboccluding ligature. Thus we may assume that in therapeutic torsion the circulation is completely destroyed, but that pathological torsion may fall short of this and produce a condition of red infarction in which infection with secondary inflammatory reaction is probable.

Embryonic Rotation.

The human embryo affords an example of rotation in the changes which occur in the position of the midgut between the fifth and tenth weeks. (Fig. 2.) Up to the former date this loop, with its artery of supply, the superior mesenteric, as its axis, lies in the sagittal plane within the coelomic cavity and is connected with the yolk-sac through the vitelline duct. Two changes now occur: the midgut loses its distal attachment within the umbilical cord by atrophy of the vitello-intestinal duct and—perhaps owing to its relative rapid increase in length—the greater part of the midgut passes through the umbilical orifice into the diverticulum of the coelomic cavity which lies in the base of the umbilical cord (Fig. 3).^{*} We do not know why the midgut passes beyond the abdominal wall; it has been suggested that this is due to the rapid increase in the size of the liver, but as the midgut is drawn back into the abdomen within a few weeks, during which time there is little relative reduction in the size of the liver, this explanation is difficult to accept. Fraser and Robbins⁷ have described the formation of traction or retention bands in the base of the mesentery at both extremities of the midgut. These approximate the duodenal and colic angles, forming a narrow isthmus to the loop; it is about this, the duodeno-colic isthmus, that rotation takes place (Fig. 4). Emphasis is laid upon the fact that rotation begins while the midgut loop is in part within the umbilical stalk, and also upon the necessity, if rotation is to be properly carried out, of the reduction of the loop into the abdomen in a set order, the last portion to be reduced being the bulky cæcum. This would suggest that a drag or obstacle to reduction is necessary for the accurate performance of rotation. This drag may be provided by the bulky cæcum fitting snugly in the umbilical ring, and it is possible that one factor in incomplete rotation may be an unduly large umbilical orifice. The effect of this drag is to keep the two limbs of the midgut parallel and near together and, with the formation of a narrow base by traction bands, to bring about physical conditions favourable to rotation—a ship only swings at anchor when the cable is taut. In Dott's⁸ opinion the left umbilical vein, carried downwards and to the right by the enlarging liver, exerts pressure on the cephalic limb of the midgut, pushing it downwards and to the right so that the caudal limb is displaced to the left. This suggestion that the position of the midgut is determined by the pressure of a soft, yielding structure, the umbilical vein, is not convincing. Fraser and Robbins suggest that the returning small intestine assists in rotation of the loop by pushing its caudal limb backwards and to the left. This explanation also is barren of proof; we know nothing of the

forces which determine the return of the small gut, and until we do we cannot with any certainty attribute any purposeful action to the bowel itself. Further, our difficulty in explaining these occurrences is not lessened by the fact that rotation of the midgut is almost constant; variations or defects are extremely uncommon, for Dott found only 45 records of gross developmental error. It is not easy to attribute to a more or less chance position of a piece of small intestine the determining of changes which so rigidly follow a uniform plan.

When the "second stage of rotation" (Dott) is complete, the midgut loop has rotated in its different parts to a variable degree, which is at its maximum some 270°, and lies in such a position that zygosis, the adhesion of opposed peritoneal surfaces, can occur (Fig. 5). Rotation of the midgut is purposeful; by whatever agency it is brought about it is very rarely imperfect. When it is the error is always one of omission; embryonic rotation is never excessive, never goes beyond the normal, and never leads to vascular changes which would imperil the vitality of the small bowel. It may be that the arterial pressure in its pedicle prevents this; if so, it exemplifies the protective mechanism of the increasing value of n (modulus of rigidity or capacity for resistance to torsion).

Rotation of the Fœtus.

Another instance of axial rotation is that which results in the numerous spirals of the umbilical cord which, according to Grosser,⁹ are left-handed in 80 per cent. These are true spirals in which both the arteries and vein are involved, as is well shown in Fig. 6, and also by an exhibit kindly lent from the museum of St. Thomas's Hospital. By some it is said that the arteries twist round the vein; this appearance is an illusion, as is shown if two pieces of coloured string are twisted with a plain thicker piece of string. If the thicker piece representing the vein be made taut, the coloured strings representing the arteries appear to twist round the vein, but if the coloured strings be pulled tight it appears that the thicker piece representing the vein is twisted round the arteries. Yet in both cases the same twist has occurred (Fig. 7). During the second and third months of its life "as an aquatic parasite within its mother," as Bland-Sutton¹⁰ so aptly expresses it, the fœtus floats freely in the amniotic fluid, and it is during this period that the spirals in the cord are produced. At first sight it appears to be obvious that they are an index of foetal activity and that the embryo paddles itself round and round, but although the foetal movements begin at a very early stage of intra-uterine life I am not convinced that they are strong enough for this purpose, even though little force would be necessary at this stage. Other movements of the fœtus, such as intra-uterine respiratory movements, including hiccough, cannot be advanced as factors in rotation, as they do not occur within the early months of intra-uterine life. In discussing the production of these twists G¹¹ hypothesises as a plausible hypothesis as a plausible hypothesis, found that, when spun with the fingers and then checked, the contents of the unboiled egg continue to rotate. According to this theory, rotary movements of the mother would occasion rotation of the fœtus, but if it be a fact that the spirals are in one direction four times out of five this explanation cannot be upheld. If we knew in which direction the limbs of the stronger side of the body would rotate the fœtus we might venture to surmise that this preponderance of left-handed spirals is associated with the preponderance of right-handedness, even though the relative proportions do not correspond.

We know one or two facts which shed some light on the method of production of these spirals and their function. The first is that the spirals never become so numerous or so acute as to cause the death of the fœtus, and the second is that should the fœtus die from another cause the spirals may increase enormously; in one specimen 350 have been

* Figs. 2, 3, 4, and 5 are reproduced from N. M. Dott's paper in the British Journal of Surgery, 1923, xl, 251.

counted.¹² This latter fact casts doubt on the hypothesis that the spirals result from foetal activity, but both statements suggest that so long as the foetus is alive there is some mechanism which hinders over-

and effect is difficult to prove, for cryptorchism is common in domestic animals¹³—e.g., the dog—yet I have been able to discover only one known specimen of axial rotation of the testis in the dog. In man,

FIG. 1.

FIG. 2.

twisting of the cord. In my opinion the chief influence can only be the flow of the foetal blood through the umbilical artery, though the length of the cord and the time factor (by which I mean the relatively slow formation of spirals) are undoubtedly important. If this argument be accepted, it supports the hypothesis that there exists in the normal blood pressure within the artery of any pedicle a natural agency by which

while torsion of the cord occurs more frequently when the testis is imperfectly descended, it may occur when the testis is in the scrotum, yet even in this case anatomical abnormalities exist similar to those present in axial rotation of an undescended testis. Every specimen I have been able to examine has confirmed this statement. No. 2079 Guy's Hospital Museum provides a good example. The patient was admitted

FIG. 3.

FIG. 4.

over-twisting is prevented and by which rotation of a degree insufficient to interfere with the blood-supply may be spontaneously reversed.

PATHOLOGICAL ROTATION.

Rotation of the Testis.

Torsion of the cord in the male with axial rotation of the testis appears to be closely associated with errors of descent. That this is an association of cause

under Mr. Howse in 1892 with the left testicle and cord greatly swollen. "both testicles had always been in the scrotum." The left testis was found twisted upon itself in the axis of the cord "three times round." The anatomical conditions are exactly those described below. Torsion usually takes place an inch or more above the testis within the cavity of the tunica vaginalis; this, the commoner type, involves the whole testis, but when the testicular mesorchium is

long, torsion may take place there, so that the epididymis is not affected.

Numerous authors have drawn attention to the fact that the rotated testis is always inverted (Godard

writers, such as Edington,¹⁵ who says "in my case the epididymis was completely intratunical," seem to regard the condition as exceptional. yet I believe it to be constant, as it occurs in every specimen I have

FIG. 5.

FIG. 6.

FIG. 8.

FIG. 6.—Radiogram of umbilical cord, in which one umbilical artery and the umbilical vein have been injected.

FIG. 8.—From W. H. A. Jacobson's "Diseases of the Male Organs of Generation." (J. and A. Churchill, London, 1893.)

used the term "reversed" in the same sense); this is proved by finding the hydatid of Morgagni below the testis (see Fig. 8). The inversion is brought about by or results in an absence of the normal adhesion of the vas to the posterior surface of the epididymis. Further, by taking into account the side to which the testis belongs and the position of the digital fossa, it is seen that the testis becomes reversed

owing to this inversion so that the right appears to be the left and vice versa.

But there is also a constant and, to my thinking, a more important abnormality of the peritoneal investment of the testis; this, instead of being reflected from the side of the epididymis on to the scrotal tunics, completely covers the testis proper and the epididymis, its reflection taking place some distance up the cord (Fig. 9). Thus there is no posterior connexion of the testis to the scrotum, and the common urogenital mesentery from which the mesorchium is derived becomes

FIG. 7.

thinned and elongated, providing a condition most favourable to rotation. As I regard this anatomical defect as the chief predisposing cause of torsion, I should like to record that it was demonstrated by the late Mr. J. H. Targett, in my student days pathological curator of the Hunterian Museum. I cannot find that he published his observation, nor is it realised by most teachers of surgical pathology. Keith,¹⁴ in his work on embryology, evidently appreciates this condition, but naturally leaves the anatomical details undescribed. Other

come across. From Keith's figure (Fig. 10) we see that the gubernaculum has failed to obtain an attachment to the testis and has picked up the vas. I have not recognised this condition in any specimen in London museums; to me it appears more reasonable to regard the gubernaculum as absent in so far as its attachment to the testis or vas is concerned, and to associate this defect with the maldescent of the organ and the abnormality of its peritoneal investment.

Even now we have only arrived at some understanding of the factors predisposing to axial rotation of the testis; of the actual exciting cause we know nothing. It is easy to realise that a testis swinging by a long mesentery in the general peritoneal cavity may become twisted by those agents which affect any similarly situated abdominal tumour, but how rotation occurs when the testis lies over the inguinal canal or in the scrotum I am unable to surmise. I find it hard to accept oft-quoted agents such as blows, and no movement of the thigh or of the abdominal wall can, in my judgment, supply the components of the couple which, according to my hypothesis, is essential for the production of rotation.

Since these pages were written and the figures prepared, Mr. Roche has published a carefully thought-out paper on this question. He appreciates most of the anatomical abnormalities to which I have drawn attention, although apparently he does not regard them as constant. He describes one rotated testis removed by himself as "not inverted"; I have been allowed to examine this specimen and

FIG. 9.

see no reason to regard it as the only exception to the uniform rule. He argues with much cogency that inversion is the result of an endeavour on the part of nature to allow an incompletely descended testis to reach the scrotum. Fascinating as this idea is, it appears to me to be untenable, owing to the fact that inversion is also present in every case of rotation of a normally descended testis.

Intraperitoneal Rotation.

We have the authority of Bland-Sutton¹⁶ for the statement that a variety of abdominal tumours and any abdominal organ except the liver may undergo rotation. He writes "that a tumour hanging freely in the belly should, by mere alteration of the position of the body or by motion imparted to it by a tumult of the bowels, spin round and twist its pedicle, is as comprehensible as the fact that a good weathercock moves in varying directions under the influence of the wind." This is an inimitable word picture, but does not help to explain the mechanics of the rotation. Axial rotation is appreciated as a clinical entity in the acute phase only, yet there is evidence that even when symptoms are recent in onset rotation has been taking place for some time. The symptoms are caused by vascular obstruction, chiefly of the veins, and until this occurs no symptoms, except brief attacks of pain, and no pathological changes in the tumour occur. While, on the one hand, rotation through more than one complete circle may cause no symptoms, "severe nutritional disturbances in the tumour" have occurred with rotation of only 120°.¹⁷ When rotation has been sufficient to interfere with the vascular supply and return of the organ or tumour concerned, acute oedema, congestion, and later necrosis occur. Provided infection is not set up, atrophy follows rotation of solid organs or tumours, but even in these infection may ensue, presumably from the adjacent bowel. Infection is inevitable when the rotated viscus is itself part of the alimentary tract and is more than probable when a cyst, such as an ovarian or fimbrial cyst, is involved. When infection of a solid or cystic body occurs, symptoms of suppuration are added to those of torsion, and when the bowel is involved symptoms of strangulation will also be present. To the slow, gradual type of torsion in which no acute vascular changes occur Bland-Sutton has applied the term "chronic." This has one result which holds out most fascinating possibilities, and that is complete detachment of the organ or tumour concerned. This must be the pathology of the small fibrous or fatty bodies which are occasionally found free in the peritoneal cavity; they may be detached appendices epiploicae.

The peritoneum surrounding larger tumours, particularly those liable to mild infection, becomes inflamed and adheres to adjacent omentum, bowel, or abdominal wall. Presumably detachment only occurs after a new circulation has been established. Alban Doran¹⁸ records several examples of this process from the practice of Mr. Bantock; one of these specimens, now in the Museum of the Royal College of Surgeons of England, shows a cyst which has acquired a new source of blood-supply from the omentum. Kelly¹⁹ figures a myomatous uterus amputated by torsion and adherent to the anterior abdominal wall.

It seems probable that any small degree of chronic rotation must cause pressure on nerve filaments which is represented to the organism as pain. This condition may account for obscure cases of acute fugitive abdominal pains without other symptoms. Cases are on record in which operation carried out solely for abdominal pain has revealed no other pathological condition than a mild degree of axial rotation of the omentum without any vascular disturbance. The day is to be anticipated when a preoperative diagnosis may be arrived at in such cases.

There is some clinical evidence that twisted pedicles may spontaneously untwist. Ol-hausen²⁰ found on

laparotomy "all the signs of torsion: green discoloration of the cyst wall and of the pedicle, the latter brittle and its vessels thrombosed. The unicellular cyst was filled with blood-stained fluid but the pedicle was not twisted." Grottenfelt²¹ has collected 13 cases of a similar kind; in each case the pedicle showed evidence of torsion from the presence of spiral grooves and ridges on its surface.

Rotation in Animals.

Axial rotation of abdominal organs is not infrequent in animals. Volvulus of the small bowel or colon is well recognised in the horse, and axial rotation of the stomach occurs in the dog and of the uterus in several animals, of which the hare is perhaps the commonest. Current books on veterinary surgery and pathology give no help in elucidating the problem in man. Much writing on veterinary pathology is not up to date in relation to human physiology and pathology, and the subject is unlikely to advance until abdominal explorations are as common in veterinary as in human surgery. Axial rotation in animals is attributed without scientific evidence to posture, falls, or over-feeding. Volvulus of the double or small colon, which is the commonest fatal intestinal affection in the horse,²² is almost always treated by manipulation through the anus, so that the exact condition present is not open to proof. Some are of opinion that

FIG. 10.

From Sir A. Keith's "Human Embryology and Morphology," (London: Arnold, 2nd Ed., 1904.)

physiological experimentation on animals has already yielded the bulk of the knowledge which it has in its power to convey to man, but even if this view be not accepted physiological experiment most urgently needs a corrective in the shape of operative observation under normal conditions. Surgical exploration of animals, beyond the benefit which would be conferred on the animal concerned, is a rich unexplored field for the benefit of mankind which, it is to be hoped, will not elude the vision of the Minister of Health for many years longer.

Rotation of Normal Organs in Man.

Of the normal abdominal organs in man which may undergo rotation the most interesting is the omentum. The factors which induce the purposeful migration of this "abdominal policeman" to different parts of the peritoneal cavity constitute a problem which cannot escape the curiosity of every surgeon, yet, as far as I can discover, no one has supplied a logical answer to it. If, as I think we must, we rely on intestinal peristalsis to supply the motive force both for protective movements and for the pathological twists which occasionally affect the omentum, we are at once embarrassed by the corollary, to which there is no answer: if intestinal movements can produce omental torsion, why is it not frequent? Is it prevented by some natural mechanism or does it require some other pathological condition to act as a "physical adjuvant"? Support is lent to the later

hypothesis by the fact, pointed out by Cowell,²³ that torsion of the omentum usually occurs when a hernia coexists. It has been suggested that the normal rotation of the midgut is in some way assisted by the umbilical ring; can it be that the neck of the hernial sac acts in the same way as a factor in the causation of pathological rotation of the omentum?

Rotation of part of the intestinal tract, as a volvulus of the small intestine, cæcum, or pelvic colon, forms a well-recognised lesion. Dott has shown that one of the important predisposing factors in the production of volvulus of the pelvic colon is a failure of the normal rotation of the midgut. As a result zygoxis—a term coined by the late Prof. Shattock to define developmental as opposed to acquired or inflammatory peritoneal adhesion—is defective and the part of the intestinal tract involved remains unduly mobile. It is suggested that adjacent coils of intestine, or an intestinal coil and the uterus, lying one on each side of the pelvic colon, form the required couple and promote rotation by their peristalsis. This seems to me to be the usual nature of all types of intraperitoneal rotation.

Axial rotation of the female pelvic organs has been recognised for nearly a hundred years.²⁴ Torsion of the uterus is particularly likely to occur in an animal with a bicornuate uterus and is also known in woman, especially in the presence of a fibromyoma of the body of the uterus which, by rising out of the pelvis, elongates and narrows the supravaginal portion of the cervix.²⁵ Conditions favourable for rotation then exist and the uterus turns to the right. It would seem that the rectum and bladder are the two forces which form the rotating couple. The bladder may play an active or merely a passive part in this process, but I see no reason to doubt that recurring distension and emptying of the bladder may exert an important influence upon rotation of the uterus.

More attention has been paid to axial rotation of pelvic tumours than to all the other forms of torsion. In Sir John Bland-Sutton's opinion rotating tumours tend to turn towards the midline; those on the right turn to the left and left-sided tumours rotate to the right. This rule is not without exceptions, for several gynaecological authorities state that the path of rotation "follows the direction of the movement of supination of the forearm of the affected side."²⁶ This question is only of interest in that it may give us some clue to the discovery of the factors which bring about rotation. The first important paper on this subject published in this country was by Lawson Tait,²⁷ who records a post-mortem on a fatal case in which rotation had taken place through four and a half complete revolutions. Any pelvic tumour which has acquired a pedicle of sufficient length and tenuity may become rotated. Cysts in the broad ligament—parovarian or fimbrial cysts—are least often affected, for they are primarily sessile and only rarely acquire long pedicles. The process seems to affect tumours of medium size; possibly very large tumours escape because they have been present long enough to form anchoring adhesions, but a normal ovary or an enormous tumour weighing 20 kg. may be involved. A thin, long, elastic pedicle will offer less resistance to any rotating force, but it will also have less power to straighten itself. On the other hand, its vessels are less likely to be obstructed from a degree of rotation which would obstruct the vessels of a thicker, shorter pedicle. Bland-Sutton and Giles²⁸ quote Spencer Wells's statement that "axial rotation has been especially noticed to follow the diminution in size of the uterus after delivery at term or abortion." It is difficult to understand how any decrease in intra-abdominal pressure can predispose to torsion. The determining factor seems to be the still forcible uterine contractions which follow labour, the necessary couple being formed by this organ and the sacral promontory.

Widely differing opinions have been expressed as to the forces which promote rotation. Following Goodsir's teaching that a law of spirality guides the growth of all organisms, Fischer²⁹ maintains that

axial torsion is a function of the living cell, that the growth of tissues takes place under constant spiral axial torsion, and that bilateral symmetrical organs rotate to that side opposite to which they belong. This theory has been applied to the growth of ovarian tumours, and is known as "Kustner's law." The acceptance of a principle like this negatives intestinal peristalsis as a cause of rotation, for peristalsis could scarcely produce uniform rotation in one direction. If we can exclude intestinal peristalsis and are dissatisfied with the hypothesis that rotation is a natural phenomenon of growth, we are forced to invoke the aid of the abdominal wall. If rotation of a given organ or tumour were always in one direction it would support the suggestion that the rectus muscle of that side, with the vertebral column, provides the couple, but the frequent rotation of small organs or tumours on which the rectus could scarcely exert any force is an argument against this view. Mayer³⁰ states that torsion is hindered when the tumour lies in the pelvis and favoured when it is in the abdominal cavity, and suggests that in the pelvis it is less affected by external influences and by intestinal peristalsis.† Freund³¹ is of opinion that ovarian tumours lying in the pelvis tend to grow down behind the uterus but later, as they enlarge and become abdominal, tend to fall forwards with their pedicles on their posterior aspects. Much has been written in support of the view that bodily movements induce rotation of abdominal tumours. The principles involved, as Mayer writes, are the transmission to the tumour of a turning movement of the whole body and the property of inertia by which the tumour continues the movement transmitted to it when the body has returned to rest.

Sellheim's findings are in favour of the influence of bodily rotation as a cause of rotation of cystic bodies, but such bodily movements as his theory demands do not occur in ordinary life, and he entirely ignores the fact that rotation takes place most frequently in ovarian fibromata,³² and is also relatively common in ovarian dermoids. The thick walls and semi-solid contents of these cysts do not fulfil the mechanical conditions demanded by his hypothesis. The hamodynamic theory of Payr³³ deserves careful consideration; by physical experiment he endeavoured to show that the cause of rotation was the difference in pressure in the veins and arteries of the pedicle respectively. He argued that when the venous circulation was once interfered with the distended vein formed a spiral round the artery, but usually these conditions do not exist in the pedicle of a rotated viscus or tumour, since both artery and vein are twisted. Apart from this, his theory is still far from supplying the real cause of rotation, for it presupposes the existence of venous obstruction, which can only occur when rotation has already begun. In my judgment there is more evidence in favour of an "internal" than of an "external" cause. I find myself unable to accept Kustner's law and see no reason to doubt that intestinal peristalsis, alone or with uterine contractions, provides the components of the couple necessary to promote rotation of pelvic tumours.

SUMMARY.

It has been my object to show (1) that axial rotation has a mechanical basis, (2) that this is founded upon the principle of the couple, (3) that

† The necessary elongation of the pedicle and the fact that when in the abdomen the tumour is more liable to be influenced by intestinal movements undoubtedly favour rotation, but that such a position is not essential is shown by cases such as the following: In 1926 I operated on a woman of 27, five months pregnant, for acute abdominal pain; attacks had recurred for three days and after 24 hours in hospital her pulse began to rise. Per vaginam a defined mass the size of a golfball could be felt in Douglas's pouch, so she was admitted as a case of appendicular abscess. On laparotomy this proved to be an intensely congested right ovary and tube of which the pedicle was twisted through two and a half circles to the left. The parts affected were removed. Owing to the size of the uterus the lower ileum, which usually occupies the pouch of Douglas, had been displaced upwards, and the right half of the pelvis was shown at operation to contain nothing but the uterus and the right tube and ovary.

the couple is provided by two contracting viscera or by one viscus and a resistance such as the sacrum, and (4) that nature has a limiting influence on rotation through the arterial circulation in all pedicles.

TOBACCO AMBLYOPIA.

By H. M. TRAQUAIR, M.D., F.R.C.S. EDIN.,

OPHTHALMIC SURGEON TO THE ROYAL INFIRMARY, AND TO CHALMERS' HOSPITAL AND POORHOUSES, EDINBURGH.

THIS paper is based on the records of the ophthalmic department of the Royal Infirmary, Edinburgh, for the years 1913 to 1926 inclusive. The work is conducted in two similar but independent clinics (designated A and B), and Table I. shows the statistics from each clinic, and also those from the two combined.

TABLE I.—*Showing Statistics from Clinics A and B, and the Two Combined.*

	A.	B.	Combined.
Total patients	55,253	52,889	108,142
Tobacco amblyopia cases:—			
Total and Percentage ..	458 (0·83)	630 (1·2)	1,088 (1·0)
Year—highest percentage ..	1914 (1·35)	1916 (2·13)	1915 (1·48)
lowest	1921 (0·21)	1922 (0·5)	1921 (0·41)
Highest month (aver. number of cases)	April (5·0)	June (4·57)	April (9·3)
Lowest month (aver. number of cases)	Oct. (1·6)	Dec. (2·0)	Dec. (3·6)
Highest age	84	79	84
Lowest age	29	23	23
Tobacco consumption—oz. per week:—			
Highest	12	7	12
Lowest	0·5	0·5	0·5
Average	3·43	2·9	3·13
Occupations:—			
Outdoor	—	—	451
Indoor	—	—	600
Not given	—	—	37
Peaks	1	5	6

The figures illustrate the different experiences which two practically identical clinics may have in the same town, each receiving patients on alternate

days of the week. It will be seen that B, which had over 2000 fewer patients, had nearly 200 more cases of tobacco amblyopia. The peak of annual incidence was two years later (1916 v. 1914) in B than in A, and was also higher, attaining the unusual figure of over 2 per cent. in 1916 in B. The lowest annual incidence was about the same time (1921) in both, but lower in A than in B (0·2 v. 0·5). The highest and lowest monthly incidences were two months later in B (June v. April and December v. October). The average age was over ten years higher in B than in A. Five female cases were recorded in B and only one in A. In reality six occurred in B but notes of one could not be found, and it was therefore not included. The average weekly consumption of tobacco was half an ounce less in B than in A. These discrepancies are of interest in so far as they reflect upon the value of the statistics. Had the figures from one clinic only been available a somewhat less informative picture would have been obtained. It would appear that there are difficulties in assessing accurately the prevalence of this disease. No special features in the two clinics can be adduced as explanatory factors. In B, which had more cases of amblyopia, the staff was constant during the period, and the patients came on Tuesdays, Thursdays, and Saturdays; in A there were several changes in the staff owing to the war and to the natural course of events, and the patients came on Mondays, Wednesdays, and Fridays.

In regard to the combined figures the following points may be noted:—

Percentage of Cases.—The records of other observers show that the numbers of cases of tobacco amblyopia in proportion to the total patients vary considerably in different places. From 0·2 per cent. to 1·4 per cent. have been recorded, and the 1 per cent. for Edinburgh is evidently a fairly high figure.

Consumption of Tobacco.—Nearly all the patients used between 2 and 4 oz. of tobacco weekly. Four cases are recorded as using $\frac{1}{2}$ an oz. and 28 as using 1 oz. Seventy-four used 5 oz. or more, and the highest figure—9 oz.—was reached in only one case. Five cases, four males and one female, were due to cigarette smoking in numbers from 130 to 280 cigarettes weekly. Four cases, two males and two females, took snuff in quantities of from $\frac{1}{2}$ to 1 oz. weekly. Only four of the six female cases were due to pipe smoking.

Usher in 1100 cases had 27 females, while Cossu had only two females in about 600 cases.

Annual Incidence.—During the 14 years from January, 1913, to December, 1926, the annual percentage of tobacco amblyopia, calculated on the total ophthalmic out-patients, varied from 0·41 to 1·48. The curve shows two peaks, one about the years 1914 to 1917 and the other in the year 1924.

Monthly Incidence.—The monthly incidence, in this case the actual number of tobacco amblyopes, shows a peak in the late spring, the highest month being April and the lowest December. It must be noted that the curve indicates the incidence of application for advice, not the incidence of onset of the amblyopia, which is considerably earlier. As the onset is gradual, patients are usually unable to give more than a vague account of the approximate time when they first noticed visual symptoms. In the presence, however, of a determining factor, such as accident or illness, the date of onset is more definite. The question is discussed, by Usher¹ who, after a careful investigation of this point in about 1000 cases, was unable to obtain reliable evidence as to the incidence of onset. In three-quarters of his cases the visual failure began six months or less before advice was sought, and in a quarter of them 12 months or more. The actual monthly incidence of onset must, therefore, be regarded as indefinite at present, nor is it possible to regard a peak in the monthly incidence of amblyopia patients as necessarily indicating a peak in onset in the same or in any other month.

The incidence of cases was found by Cossu² to be highest in May and lowest in December, while Usher

of the plotted ages is rather steeper than that found by Usher and Elderton¹; there were only 14 patients over 75 and only nine under 30, Usher's corresponding figures being 37 and 23, although 150 fewer cases were included. The peak, as in Usher's statistics, occurred at the 50 to 54 period, which included 199 patients (Usher, 145).

pursuits they have been arranged into groups as large as possible, no doubt with the sacrifice of a slight degree of accuracy. A preponderance of about 14 per cent. in favour of indoor occupation was found, but as a large proportion of the industrial population is engaged in indoor work, this does not seem to be enough to indicate that indoor occupation per se especially favours the production of amblyopia. Without accurate information as to the numbers employed in each industry the effects of occupation are difficult to estimate. If we consider the large numbers of miners in the district it is evident that they are probably less prone to tobacco amblyopia than, for example, those employed in the spirit trade or caretakers, although the absolute figures favour the miners. On the whole the figures suggest that sedentary and confined occupations are apt to provide suitable conditions for the development of the disease.

No evidence was found to suggest that exposure to light has any influence in producing the condition. This is in accordance with the findings of Usher. As the macula is the part of the retina which is most exposed to light the disease should begin there if light were a potent factor, but, unfortunately for the light causation hypothesis, this is not the case (Traquair²).

In my private practice the proportion of tobacco amblyopia cases has varied round about 0.5 per cent., but is increasing since panel patients have been coming for ophthalmic benefit. The number of cases is too small to enable any conclusions to be drawn, but retired army officers and hotel keepers occupy a prominent position.

Different views prevail as to the extent to which the consumption of alcohol is concerned in the production of what is often called "tobacco-alcohol" amblyopia, or sometimes "alcohol" amblyopia. A few observers hold that the condition is purely alcoholic, others that tobacco is the sole factor, while the majority of ophthalmic surgeons appear to believe that both agents are concerned. On the continent and in America the influence of impure alcohol is widely held to be an important factor, while in Britain many oculists believe that the rôle of alcohol is only secondary in so far as it depresses the health and reduces resisting power. It has also been stated that the moderate use of alcohol renders smokers less liable to develop tobacco amblyopia. Usher and Elderton, in an analysis of 1100 cases, found no evidence to indicate that alcohol was a direct factor in the production of amblyopia. One hundred and twelve of their cases were total abstiners.

The question of the influence of alcohol was thoroughly discussed from the clinical point of view

Tobacco amblyopia .. Average of total cases 1913-26.
 Arrests for drunkenness " " " " 1923-26.
 " " (m. s.) " " " " 1923-26.

Chart showing monthly incidence of tobacco amblyopia and arrests for drunkenness during the periods 1913-26 and 1923-26. The roman numerals on the right of the chart refer to methylated spirits (m. s.).

by the Ophthalmological Society of the United Kingdom³ in 1887; yet, in spite of the very definite opinions expressed at that time against the importance of alcohol as a factor, much difference of opinion still seems to prevail. In order to obtain evidence bearing upon this point I have obtained the police statistics of drunkenness in Edinburgh for the years 1913 to 1926, including those of drunkenness due to methylated spirit for the years 1923 to 1926. Although it is readily admitted that statistics of arrests for drunkenness may not indicate correctly the amount of alcoholism of the kind which might be expected to give rise to amblyopia, it seems probable that the arrests for drunkenness will, on the whole, vary in a more or less parallel way with the general alcoholic

consumption in the working-class community, among whom the great majority of cases of tobacco amblyopia arise. It must also be remembered that the figures for drunkenness are derived from Edinburgh, while those for amblyopia include the surrounding district.

On comparing the annual and monthly curves of arrests for drunkenness with those of tobacco amblyopia,

FIG. 3.

Chart showing age of patients in 1088 cases of tobacco amblyopia.

opia, it will be seen that the annual incidence for drunkenness due to alcohol declines sharply between the years 1914 and 1918, rises again to 1920, and then gradually falls. The monthly incidence rises, although somewhat unevenly, from February to December, and is low in spring and early summer. The annual incidence for arrests for drunkenness for the years 1913 to 1926 corresponds to the incidence of arrests for all crimes and offences. The drop to 1918 is probably largely if not entirely due to the fact that the potential drunkards and other misdemeanants were nearly all under military control of one kind or another. After 1918 they began to be set free, and arrests for drunkenness and crime began to rise, but tobacco amblyopia continued to fall until 1921—the year of the coal strike. Then tobacco amblyopia began to rise again fairly rapidly, while arrests for all offences and for drunkenness were falling.

For methylated spirit, unfortunately, the figures for the last four years only are available. Up to 1923, drunkenness from this cause had been increasing and the police report for that year states that 20 per cent. of drunkenness was estimated to be due to methylated spirit. From 1923 to 1924 the figures show a rapid decline, while amblyopia was rising until 1924. The monthly incidence shows its acme in March but, unlike the incidence of amblyopia, falls during the summer months. If, in order to improve the comparison, the figures for 1923 to 1926 only are used in estimating the monthly incidence of tobacco amblyopia, the graphs still show nothing suggesting any relationship (Fig. 2). Though these figures are based on data which do not in all respects permit of exact comparison, they may be regarded as at least providing no indication of any connexion between drinking and amblyopia. There are other reasons which support this view. The patients suffering from amblyopia belong almost entirely to the respectable working-class, and the kind of individual who may be regarded as a "soaker" or "waster," and who is frequently in the police-court, is seldom found amongst them. These people are met with in the surgical out-patient department and do not appear to suffer from amblyopia: many of them are women, and if drinking had much influence in the production of amblyopia more female cases

would surely occur. The high percentage of amblyopia in a respectable, not hard-drinking community, in which wood spirit poisoning is a rare and isolated occurrence, also suggests that alcohol is not a direct factor.

The graphs for tobacco amblyopia and drunkenness show a parallel decline and rise with a three-year interval; whether this has any significance the evidence obtainable does not show. No evidence of any value could be obtained bearing on the state of the public health during the period under consideration, as the insurance statistics are not regional. If such statistics were obtainable it might be of interest to ascertain whether any relationship exists between the general health of a community and the incidence of tobacco amblyopia. The amount of poor relief granted followed the drunkenness curve almost exactly up to 1920, but in 1921 the coal strike confused the issue. The poor relief curve was, no doubt, also influenced by the war.

To summarise: a relationship was found between crime, drunkenness, and poor relief, but none between tobacco amblyopia and any of these factors.

I am informed that *all* (no doubt an exaggeration) french polishers drink methylated spirits and, curiously enough, in the whole 1088 patients there is not a single french polisher.

I have notes of three cases of alcohol poisoning:—

1. Male, age 28, hairdresser, Columbian spirits drunk by mistake. Acute blindness followed by slight recovery with permanent optic atrophy. Royal Infirmary.
2. A man of 40, seen privately; a heavy drinker, who had consumed about a pint a day of methylated spirit for four months. Then, one night, rapid and complete blindness, swelling of optic discs, no recovery, permanent optic atrophy.
3. A man, about 40, seen in poorhouse. Used to be a dispensing chemist and drank methylated spirit. When seen he was almost totally blind and had permanent optic atrophy.

The clinical picture of these cases is totally different from that of tobacco amblyopia, and it appears

FIG. 4.

Tobacco amblyopia ..
Arrests for drunkenness .. } 1913-26.
(meth. sp.) : : : : : 1923-26.

Chart showing total cases per year. The figures on the right (200-500) refer to methylated spirits.

that large amounts of methylated spirit must be consumed before amblyopia is produced.

No evidence was elicited to suggest that in the district either an increased incidence or an aggravated form of amblyopia occurred during the war years, an occurrence which might be attributed to the adulteration of alcoholic drinks with impure alcohol containing wood spirit, as was found by Blegvad and Rønne in Denmark. It is evident that the rôle of alcohol

varies according to locality and is dependent not so much on the amount of alcohol consumed as on its purity. In those countries in which impure alcohol is sold and in which wood spirit poisoning is not uncommon, it is to be expected that the consumption of certain alcoholic drinks will be an important factor in the amount or the character of toxic amblyopia. In Britain, and certainly in the Edinburgh area, the amount of wood spirit is minimal, and the part played by alcohol may also be regarded as minimal—that is to say, we have here to deal with a pure tobacco amblyopia.

Clinical Features.

The symptoms described by the patient, together with his history, appearance, and circumstances, build up an extremely characteristic picture. Among the initial symptoms three are more or less prominent. Perhaps the most common is a complaint of "misty" vision; the patient states that he cannot recognise the faces of his friends. In other cases difficulty in reading is the first symptom noticed. This appears to be not quite so frequent an initial symptom as the misty vision; no doubt a good deal depends upon the reading habits of the patient and upon the state of his distant vision under normal circumstances. A third initial symptom is "dazzling" in sunlight. What precisely is meant by "dazzling" is difficult to define accurately. I incline to think that it means that when the pupil is contracted in sunlight the patient seems to see a bright silvery fog between him and objects.

Difficulty in connexion with work is rarely complained of unless the work is of a kind that requires good vision—e.g. the compositor does not see his type properly, and the carpenter does not see his rule. The high degree of amblyopia from this cause which is compatible with labouring work, or even with the work of a gardener, is often surprising.

The character of the visual loss is shown by the patient's hesitation and the mistakes he makes when reading Snellen's test types. He has difficulty in reading the letters which are towards his temporal side. It is also well brought out by a simple test of the light-difference sense, as by Bjerrum's types, which are grey on grey. The tobacco amblyope who can read the ordinary Snellen's card fairly well can see none, or only one or two, of the letters of the Bjerrum's type. Very often there is also a disproportion between the distant vision by Snellens type and the reading vision, the latter being considerably worse than the former would suggest. Indistinct or soiled print is read with unduly great difficulty.

The visual loss has nearly always been present for some time before the patient seeks advice. When he does so, both eyes, in my experience, are always affected, though the defect may be very slight in one. Evidently the disease often begins unilaterally, although this stage does not come under observation.

Many tobacco amblyopes exhibit a striking absence of anxiety about their vision, which makes it difficult to get them to return for re-examination and makes them reluctant to stop their tobacco. Only in the more severe cases does the patient appear to be at all disturbed about his sight. I have persuaded some of these patients—often with some difficulty—to let me examine them again and have found them still smoking, but seeing well enough to do their work and enjoy themselves. Cases of Leber's disease and other forms of bilateral visual failure manifest quite a different attitude. It would appear that a degree of tolerance can be established and that the disease does not progress to the same extent in all cases, even though the use of tobacco is continued. The course of some cases even suggests that spontaneous improvement may occur, with little or no diminution in tobacco consumption, a feature which is probably due to improvement in the patient's general health and resisting power. No case ever progresses to complete blindness.

A very common statement, so common as to be not without value in diagnosis, is that the amount of tobacco used was reduced some weeks before advice was sought, and nevertheless the vision became worse. Also, when the patient after the first consultation has stopped tobacco entirely, the visual defect is not infrequently found to be no better, or even worse, at the second visit six or eight weeks later. This indicates that the poison takes some time to produce its effect and suggests that it is cumulative in its action. It also shows the necessity of making careful inquiries, as the patient tends to state the amount of tobacco he is using at the time of his consultation. In one case, for example, a patient who had both chewed and smoked heavily only developed the amblyopia seven months after reducing his consumption to 2 oz. weekly.

The general health is of great importance. Tobacco amblyopia appears at about that period in life when the physical powers are failing, and in many cases it is possible to obtain a history of some illness preceding the visual defect. This is a factor which probably influences the early summer incidence of the disease, as illness is more common in the winter and early spring. In patients whose systems are saturated by years of tobacco consumption up to, or nearly up to, the limit of their individual tolerance—a limit which is declining as the years advance—a determining factor may easily arise. This factor may be an illness, an accident, or merely a psychological disturbance. One of my private patients missed his footing on attempting to board a moving tramcar and fell; though only a little shaken, he promptly developed amblyopia. An important condition is arterio-sclerosis. Smokers whose health is gradually becoming impaired from this cause are liable to become amblyopic, and this is, I believe, the explanation of the presence, often observed, of hæmorrhages in the retina of tobacco amblyopes. I have seen tobacco amblyopia in tabes and in diabetes, and in the cases which came under my notice I have regarded the general disease as the determining factor. Though always on the look-out, I have not yet seen a scotoma in diabetes or in tabes which was the direct result of either of these diseases. That a high degree of idiosyncrasy exists in different subjects is well recognised, but some additional determining factor will often be discovered when the tobacco consumption is low.

The characters of the field defects have been frequently described, but appear still to be incompletely realised. Although the true incidence of the disease upon the visual nerve elements was demonstrated many years ago (Bär,⁶ Groenouw,⁷ and Nelson⁸), the macular fibres or cells are still often regarded as those primarily concerned. This misconception has led in the past to unjustifiable theories of causation and still produces much confusion of thought both in diagnosis and ætiology. It cannot be too strongly emphasised that the macular elements, whether cells or fibres, are never either the first or the most severely affected, but are always involved after other elements of the papillo-macular bundle. If the scotoma in a case of moderate severity is carefully examined, the densest areas will be found near the blind spot or between it and the fixation area, not blind spot or between it and the fixation area, not at the fixation area itself. Only when the diffuse margin of the scotoma begins to invade the fixation area does the patient complain of symptoms, and indeed the scotoma may have existed and cleared up without the fixation area itself ever having been perceptibly affected. The scotoma of tobacco amblyopia is therefore not a central scotoma in the true sense, but a temporo-caecal defect which, by extending over the fixation area, becomes a centrocaecal scotoma.

Diagnosis.

As a rule the diagnosis presents no difficulty. In apparently unilateral cases great care is required in the examination of the apparently unaffected eye, and Bjerrum's screen and small test objects are necessary. There may be no defect of central vision by Snellen's test types.

The only conditions which may possibly give rise to confusion are bilateral affections of the optic nerves. Of these only a few cases among males fit the general clinical picture sufficiently closely to give rise to any doubt. In actual experience I have found that cases of chiasmal interference due to pituitary disease or other causes, and cases of scotoma due to Leber's disease or similar in type, are those which most commonly give rise to uncertainty. The chiasmal group is distinguished by the quadrantic nature of the scotoma and by the presence of other characteristic field changes. Cases belonging to this group are much better understood now, and are therefore more readily recognised than they were a few years ago, so that this cause of difficulty is disappearing. The Leber group gives more trouble, especially those cases which occur about the age of 40, and, while conforming otherwise to the Leber type, present no disc changes or suggestive family history. I have always found the scotoma in these cases to be more dense and more defined than that of tobacco, while the field changes immediately around the scotoma are different. It is no doubt this class of case which has given rise to the statement that toxic amblyopia exactly like that of tobacco may occur in patients who have never used tobacco or alcohol. Personally, I have never seen such a case, nor have I ever read a report of a case of this kind in which the field changes and the clinical picture were described in a sufficiently detailed way to enable a proper comparison to be made with those of tobacco amblyopia. If, in addition to the field changes, the clinical picture as a whole is considered, cases in which a real diagnostic difficulty arises must be extremely rare. These are mostly among patients with large and dense scotomata.

Prognosis.

The prognosis is good except in advanced and severe cases with pallor of the discs, more especially in patients of enfeebled physical condition. In some of these permanent impairment of central vision remains, so that distant vision is reduced to 2/60 or 3/60 and reading to the slow deciphering of large print. Progress may be slow and hope should not be given up until several years have elapsed without improvement. For example:—

1914 v. = Fingers at 2 m.

1915 v. = 6/60.

1917 v. = 6/24 stationary.

Cases in which serious visual incapacity remains appear to be rare in relation to the frequency of the disease.

Lastly, the economic aspect of tobacco amblyopia merits some consideration. From the clinician's point of view it is evident that in many directions inefficiency, loss, and waste of money and time are produced. Is the subject of any interest to the insurance societies or to the Ministry of Health?

I have to thank Dr. J. V. Paterson and Dr. A. H. H. Sinclair for allowing me to use their records.

A PNEUMATIC BONE OPERATING SET.

By W. H. OGILVIE, M.D., M.Ch. Oxf.,
F.R.C.S. Eng.,

ASSISTANT SURGEON TO GUY'S HOSPITAL.

BONE surgery approaches more nearly to pure carpentry than any other branch of the art, and success depends to a greater extent upon accurate operative detail. Many of its more recent developments have been made possible by the introduction of engineering tools, which not only eliminate much hard manual work, but allow a higher degree of perfection and accuracy in performance. Arbuthnot Lane brought into common use many of the tools of the carpenter, and Albee followed with the electrically driven bone operative set, an instrument which made possible many advances in bone surgery, but which has several disadvantages. It is expensive in first cost and in repairs. A supply of electric current is essential, and even where electricity is available, the voltage may be unsuitable, and a variable resistance must be carried. It is cumbersome, and sterilisation is unsatisfactory; the shell must be slipped over an unsterile motor, and the leads have to be draped in towels. It has to work at high speed, and consequently generates much heat at the cutting edge. It cannot be applied in many cases where mechanical aid is most needed—e.g., in a deep wound, or when obliterating and rounding off the dense-walled cavities in a chronically infected bone.

The difficulties encountered in operating on an old-standing abscess in the shaft of a long bone, enclosed in a wall of ivory consistence, led me in 1925 to consider the possibility of applying to bone surgery the principle of the pneumatic hammer which is in everyday use in road-breaking, and thus utilising a source of power which is available in every hospital in the form of cylinders of compressed nitrous oxide or oxygen. I was fortunate, through the help of Mr. J. M. Hulett, a student at Guy's Hospital, in finding an engineer who was willing to carry out the experimental work and design an apparatus suitable to surgery. After some experiments the Boyer hammer was adapted for use with surgical instruments, and has proved eminently satisfactory at Guy's Hospital since March, 1927. I hesitated at the time to place the instrument before surgeons because its applications were restricted. A mechanical bone operative set should be able to do everything that may be required in the surgery of the skeleton, and to do it better than it can be done by hand. During the past year detailed improvements to the original hammer and the addition of a pneumatic drill have so far increased the field of usefulness of the pneumatic apparatus that it now claims to satisfy these requirements.

The Supply of Pneumatic Pressure.

Pneumatic tools in industry are supplied with air under pressure by a motor-driven compressing plant. Such a plant could easily be installed in a hospital, but the apparatus could then only be used in one theatre, and the compressed air would contain all the bacteria of room air. Cylinders of compressed air, as supplied by the British Oxygen Co., provide the best source of pneumatic pressure for a surgical instrument. The air in these cylinders is sterile; it is also free from moisture, and is therefore more suitable for use in finely adjusted machinery than compressed atmospheric air. The cylinders most commonly used contain 40 and 100 cubic feet of air at 120 lb. pressure, and cost 4s. per 100 cubic feet to renew. Either can be carried in a car, and suffices for several ordinary operations. Larger cylinders can be obtained for hospital use. Although no explosion has yet occurred with oxygen when liquid paraffin has been used for lubrication, the margin of safety is probably a small one, and cylinders of compressed oxygen should therefore be avoided; in an emergency nitrous oxide could be safely used.

varies according to locality and is dependent not so much on the amount of alcohol consumed as on its purity. In those countries in which impure alcohol is sold and in which wood spirit poisoning is not uncommon, it is to be expected that the consumption of certain alcoholic drinks will be an important factor in the amount or the character of toxic amblyopia. In Britain, and certainly in the Edinburgh area, the amount of wood spirit is minimal, and the part played by alcohol may also be regarded as minimal—that is to say, we have here to deal with a pure tobacco amblyopia.

Clinical Features.

The symptoms described by the patient, together with his history, appearance, and circumstances, build up an extremely characteristic picture. Among the initial symptoms three are more or less prominent. Perhaps the most common is a complaint of "misty" vision; the patient states that he cannot recognise the faces of his friends. In other cases difficulty in reading is the first symptom noticed. This appears to be not quite so frequent an initial symptom as the misty vision; no doubt a good deal depends upon the reading habits of the patient and upon the state of his distant vision under normal circumstances. A third initial symptom is "dazzling" in sunlight. What precisely is meant by "dazzling" is difficult to define accurately. I incline to think that it means that when the pupil is contracted in sunlight the patient seems to see a bright silvery fog between him and objects.

Difficulty in connexion with work is rarely complained of unless the work is of a kind that requires good vision—e.g. the compositor does not see his type properly, and the carpenter does not see his rule. The high degree of amblyopia from this cause which is compatible with labouring work, or even with the work of a gardener, is often surprising.

The character of the visual loss is shown by the patient's hesitation and the mistakes he makes when reading Snellen's test types. He has difficulty in reading the letters which are towards his temporal side. It is also well brought out by a simple test of the light-difference sense, as by Bjerrum's types, which are grey on grey. The tobacco amblyope who can read the ordinary Snellen's card fairly well can see none, or only one or two, of the letters of the Bjerrum's type. Very often there is also a disproportion between the distant vision by Snellens type and the reading vision, the latter being considerably worse than the former would suggest. Indistinct or soiled print is read with unduly great difficulty.

The visual loss has nearly always been present for some time before the patient seeks advice. When he does so, both eyes, in my experience, are always affected, though the defect may be very slight in one. Evidently the disease often begins unilaterally, although this stage does not come under observation.

Many tobacco amblyopes exhibit a striking absence of anxiety about their vision, which makes it difficult to get them to return for re-examination and makes them reluctant to stop their tobacco. Only in the more severe cases does the patient appear to be at all disturbed about his sight. I have persuaded some of these patients—often with some difficulty—to let me examine them again and have found them still smoking, but seeing well enough to do their work and enjoy themselves. Cases of Leber's disease and other forms of bilateral visual failure manifest quite a different attitude. It would appear that a degree of tolerance can be established and that the disease does not progress to the same extent in all cases, even though the use of tobacco is continued. The course of some cases even suggests that spontaneous improvement may occur, with little or no diminution in tobacco consumption, a feature which is probably due to improvement in the patient's general health and resisting power. No case ever progresses to complete blindness.

A very common statement, so common as to be not without value in diagnosis, is that the amount of tobacco used was reduced some weeks before advice was sought, and nevertheless the vision became worse. Also, when the patient after the first consultation has stopped tobacco entirely, the visual defect is not infrequently found to be no better, or even worse, at the second visit six or eight weeks later. This indicates that the poison takes some time to produce its effect and suggests that it is cumulative in its action. It also shows the necessity of making careful inquiries, as the patient tends to state the amount of tobacco he is using at the time of his consultation. In one case, for example, a patient who had both chewed and smoked heavily only developed the amblyopia seven months after reducing his consumption to 2 oz. weekly.

The general health is of great importance. Tobacco amblyopia appears at about that period in life when the physical powers are failing, and in many cases it is possible to obtain a history of some illness preceding the visual defect. This is a factor which probably influences the early summer incidence of the disease, as illness is more common in the winter and early spring. In patients whose systems are saturated by years of tobacco consumption up to, or nearly up to, the limit of their individual tolerance—a limit which is declining as the years advance—a determining factor may easily arise. This factor may be an illness, an accident, or merely a psychological disturbance. One of my private patients missed his footing on attempting to board a moving tramcar and fell; though only a little shaken, he promptly developed amblyopia. An important condition is arterio-sclerosis. Smokers whose health is gradually becoming impaired from this cause are liable to become amblyopic, and this is, I believe, the explanation of the presence, often observed, of hæmorrhages in the retina of tobacco amblyopes. I have seen tobacco amblyopia in tabes and in diabetes, and in the cases which came under my notice I have regarded the general disease as the determining factor. Though always on the look-out, I have not yet seen a scotoma in diabetes or in tabes which was the direct result of either of these diseases. That a high degree of idiosyncrasy exists in different subjects is well recognised, but some additional determining factor will often be discovered when the tobacco consumption is low.

The characters of the field defects have been frequently described, but appear still to be incompletely realised. Although the true incidence of the disease upon the visual nerve elements was demonstrated many years ago (Bär,⁶ Groenouw,⁷ and Nelson⁸), the macular fibres or cells are still often regarded as those primarily concerned. This misconception has led in the past to unjustifiable theories of causation and still produces much confusion of thought both in diagnosis and ætiology. It cannot be too strongly emphasised that the macular elements, whether cells or fibres, are never either the first or the most severely affected, but are always involved after other elements of the papillo-macular bundle. If the scotoma in a case of moderate severity is carefully examined, the densest areas will be found near the blind spot or between it and the fixation area, not at the fixation area itself. Only when the diffuse margin of the scotoma begins to invade the fixation area does the patient complain of symptoms, and indeed the scotoma may have existed and cleared up without the fixation area itself ever having been perceptibly affected. The scotoma of tobacco amblyopia is therefore not a central scotoma in the true sense, but a temporo-caecal defect which, by extending over the fixation area, becomes a centrocaecal scotoma.

Diagnosis.

As a rule the diagnosis presents no difficulty. In apparently unilateral cases great care is required in the examination of the apparently unaffected eye, and Bjerrum's screen and small test objects are necessary. There may be no defect of central vision by Snellen's test types.

instrument with a rotary action to be fitted, whatever the shape of its shank. The control of speed which is possible in the pneumatic drill has proved of great benefit. There is no tendency for drills to jump when first applied to bone, for they are pressed against it at a slow speed of rotation, and the plunger is fully depressed only when the point of the tool has entered the bone.

Two new instruments have been made for the apparatus, a screw-holding driver and a hand-guard, for use with the saw in cranial surgery. The screw-driver works inside a hollow cylinder, which terminates in a cone-shaped collar (Fig. 2 c). When this cylinder is pressed down, the head of any size of bone screw can be slipped into position in the cone through a lateral slot, and, when pressure is released, it is held firmly against the screw-driver by the pressure of a spring. As soon as the screw has been driven in it is released by tilting the driver sideways, making the head come out through the slot. The spring retracts the collar, allowing the blade of the screw-

FIG. 3.

Hand-guards, for protection when using circular saw.

driver to project, and the screw is driven home. With this tool a large number of screws can be inserted in a very short time.

The hand-guards are used in fashioning osteoplastic cranial flaps. Surgeons have hitherto been afraid to use a motor-driven circular saw for this purpose because of the danger of tearing the dura and of wounding the scalp flap or the hands of the assistant, should the saw jump the bone. The nicety of control which is allowed by the light weight of the pneumatic drill and the exactness with which its speed can be regulated do away with these dangers. To fashion an osteoplastic flap, drill-holes are first made down to the dura with the Hudson burr, outlining the proposed flap. A dura mater protector of thin spring steel is then worked from one hole to the next between the dura and the bone. The hand-guards are slipped over the projecting ends of the protector, and an assistant, grasping the knobs of these guards, steadies the patient's head and holds the protector in position, while a bevelled cut is made with the circular saw from one hole to the next (Fig. 3). By this means an osteoplastic flap of any shape and dimensions can be rapidly cut without any risk of damage to underlying membranes.

Notes on the Use of the Pneumatic Operative Set.

The pneumatic operative set is universally applicable to bone surgery, inexpensive, and thoroughly reliable. The motive power for its use can be found everywhere where surgery is possible. Both tools are sturdy and simple, and can be sterilised by heat. The efficiency of an instrument actuated by gas pressure depends upon the smooth working of parts which are a gas-tight fit and which will be impaired by distortion or rust; therefore excessive heat or boiling must be avoided. Dry heat or immersion in lysol are the best means of sterilisation. The air in the cylinders is sterile, but after passing through the pressure gauge may contain a very small number of organisms; these can be removed by inserting a small metal chamber containing glass wool between the gauge and the tubing which leads to the instrument (Fig. 1 c). Before use a few drops of sterile liquid paraffin should be put into the air inlet and blown through by air pressure.

The hammer is operated by placing the chisel in firm contact with the bone, so that the piston is pushed to the top of its working stroke, and then depressing the air valve in the handle; air should not be admitted until the chisel is actually pressing on the bone. As soon as the cut is finished the valve should be released. The efficiency of cutting is only maintained if the hammer returns freely after each blow, and ceases if the chisel jams. Therefore the tool should not be driven deeply into the bone, but nearly parallel to its surface. In this way shavings of bone 2 or 3 millimetres in thickness can be

removed with great rapidity and under perfect control. The hammer and the tools it works are of great service in operations for acute or chronic osteomyelitis, in cutting large and uniform osteoperiosteal grafts, in cuneiform osteotomy, and in the operations of arthrodesis and arthroplasty. The small rapid blows of the instrument drive the tool steadily through dense bone with the precision of a sharp instrument cutting soft tissues. There is no danger of driving the edge too far, as may occur with the single powerful blows delivered by a hand mallet. The cut surface is smooth and regular; thus the reshaping of an articular end in arthroplasty can be done in a way that is impossible with hand work. The hammer consumes much more air than the chisel, and some escapes even when it is idle; it is therefore advisable to close the valve of the cylinder when it is not in use.

The drill is extremely economical in air consumption, and there is no appreciable leakage, so that the cylinder may be left turned on during intervals in the work. The barrel of the tool may be grasped in the hand, like the handle of a tennis racket, and the control valve regulated by pressure of the hypothenar eminence. For drilling it may be held vertically and the valve worked by the index finger. It should be remembered that Morse drills are designed to cut their own channel, and will work most efficiently if allowed to do so; additional pressure may lead to jamming in the bone.

In bone-grafting, cranial surgery, and in the operative treatment of fractures this tool lightens labour and produces better work than those operated by hand.

The pneumatic operative bone set was shown before the Orthopaedic Section of the Royal Society of Medicine in December, 1927, and before the Association of Surgeons in May, 1928. It is made by Down Bros., St. Thomas's-street, London, S.E. 1.

ON THE STANDARDISATION OF THE FEMALE SEXUAL HORMONE.

ESPECIALLY OF PURE WATER-SOLUBLE PREPARATIONS
(MENFORMON).*

BY PROF. ERNST LAQUEUR, M.D.,

AND

S. E. DE JONGH, M.D.

(From the Pharmacotherapeutical Laboratory, University
of Amsterdam.)

THE increasing importance of the standardisation of the female sexual hormone from the pharmacological as well as from the clinical point of view, together with the appearance in commerce of several preparations with different activities, expressed in so-called "units," made it seem desirable to define the unit as exactly as possible and to establish a method by which it could be determined. The method, of course, must be based upon the well-known fact, first used for the purpose by Allen, Doisy, and others, that material containing this hormone is able to reproduce oestrus in castrated female rats and mice, as seen microscopically in stained vaginal smears. Their provisional definition: that a unit be the smallest amount of substance capable of producing oestrus in a castrated rat or mouse, needs amplification in various directions. It should mention which microscopic picture is to be taken as the limit reaction; how many animals at least should be used for every standardisation, and how many of these at least should show the limit reaction; and the method by which the substance is brought into the animal body. From our extensive experience (standardisation of about 8000 batches, more than 250,000 smears) we thought

* Abstracted from a paper appearing in the Journal of Pharmacology and Experimental Therapeutics.

Description of the Apparatus.

Regulation of Pressure.—A twin pressure gauge is fitted to the gas cylinder (Fig. 1 B). When the tap of the cylinder is turned on the first dial indicates the pressure of air in the cylinder. By a screw on the top of the gauge the pressure of the escaping air can be regulated to any desired figure, the amount appearing on the second dial.

Connecting Tubes.—These are of rubber and canvas, and may be sterilised by boiling (Fig. 1 E). At each end is a gas-tight coupling, connected by a half-turn. The male end of each connexion carries a valve, which is only opened by pressure of the female end against a central pin. Thus it is possible to disconnect the tubing and to change from one instrument to another without shutting off the supply of air at the cylinder. One end of this tubing is attached by the surgeon to the instrument; the other is fixed by an assistant to the connexion on the cylinder.

The Hammer.—This is the Boyer F. hammer with pistol grip, which has been polished and plated externally to give it an aseptic finish, and has been modified in certain details to adapt it for surgical work (Fig. 1 D). The essential working parts are a heavy piston, which forms the hammer, travelling up and down in the barrel of the tool with a stroke of approximately one inch, and a small cylindrical valve set vertically in its base, which admits air under pressure behind the piston in the working stroke, and is moved to the exhaust position by a jet of air passing up a channel in the casing through a port uncovered by the piston at the bottom of its stroke. Air

is admitted to the hammer by pressure of the thumb on a lever in its handle. By a screw adjustment at the bottom of the handle the strength of blow can be varied from a gentle tap, suitable for mastoid work, to full force. The hammer has been fitted with a collar to take the tools.

The tools have a cylindrical shank, in which a slot is cut, fitting into the collar in the hammer. Into this slot is slipped a pin, which passes through a hole in the collar, and is held in position by a spring catch. The pin allows the tool to travel up and down for the length of the slot, but prevents it being driven out by the force of the blow; the slot determines the length of travel and prevents rotation of the tool on its axis. Four different positions of the pin in the collar allow the cutting edge of the tool to be set at four different angles to the handle. The tools which have

been found most useful are gouges and chisels of the Albee type, and a small mastoid gouge.

The Drill.—The drill is an adaptation of the Desoutter pneumatic drill, which is manufactured for small work in

FIG. 2C.

The pneumatic drill: A, Fitted with side handle, and Albee's twin saw. B, With Cryer's cranial osteotome. C, Screw-driver, to hold screw in position and turn same.

machine shops (Fig. 2). It consists essentially of a block of five small cylinders, disposed round a central axis, the pistons acting directly on a double spiral cam, which is fixed to the spindle carrying the chuck for the tools. For surgical work the drill has been fitted with an Albee chuck to take the saws and drills which are used with the electrical instrument. The air inlet has been made to fit the quick connexion of the tubing, leather washers have been replaced by asbestos, and the instrument is enclosed in a fluted casing which gives a comfortable grip and is easily cleaned. The drill weighs less than two pounds and lies comfortably in the hollow of the hand. The torque is very smooth and quite free from vibration, and the speed of rotation can be adjusted, from zero to 2400 revolutions per minute, by regulation of

FIG. 2B.

the amount of air admitted. The air is controlled by a plunger depressed by a spring button. All the parts are of sturdy construction, and there is nothing to wear out.

All the tools commonly used with the electric motor can be used with the pneumatic drill. A universal chuck, which may be coupled to the Albee chuck, allows any

the results obtained in various countries agree very closely (America, England, Germany, Holland, Latvia), so that the need for an international standard preparation seems less than in the case of, say, insulin. Solutions ready for use are preferable; they should contain one mouse unit in 0.3 c.cm. of oil or 0.6 c.cm. of water, in ampoules of 5 and 10 c.cm., so that six to ten animals can always be injected simultaneously. We shall be glad to send such standard solutions to any colleague who applies. It would be possible with these solutions to ascertain whether the sensitiveness of the animals is really the same in all countries. For that purpose several series, of six or even twelve animals each, should be injected with 1 unit per animal on different days. When 30 or 60 animals had been tested in this way, the results should be calculated, to see whether they agreed with the 75 per cent. of positive results required by the definition. If 1 unit of the standard preparation yields constantly consistently higher or lower percentages, we should be grateful if the investigator would communicate with us. It is in these cases that the value of a standard preparation would be obvious. For, given exactness in standardisation, it seems superfluous to require injection of the standard side by side with the substance to be tested at every standardisation, as is indispensable, for instance, with insulin. It is sufficient to adhere to the definition given above: *1 unit is the smallest amount of a*

solution that under the precautions mentioned (adequate fractionation, sufficient number of observations, &c.) produces positive smears (as defined above) in 75 per cent. of well-castrated animals. "Well"-castrated animals are those that on daily control during at least four weeks do not show any smear containing more than about 30 per cent. of epithelial cells. Two sets of six such animals each should be injected on different days, after the probable strength has been estimated from a few preliminary experiments upon three animals each. The amount of liquid injected should contain 1 unit and no more than ten animals should become positive. A lower limit of eight is only to be accepted if at least two out of the four "non-positive" animals show a recognisable effect. Only solutions should be injected on the morning and evening of the first day and in the morning of the second; aqueous solutions are injected morning and evening of the first day, morning, noon, and evening of the second, and in the morning of the third. Smears should be stained by the "Giemsa" method.

Summary.

The method of standardisation of the female sexual hormone outlined by Allen, Doisy, and others has been developed with the help of experimental data gained by very extensive experience. Definite directions are given and a standard preparation is put at the disposal of other workers in the same field.

Clinical and Laboratory Notes.

NOTE ON THE IMPORTANCE OF SLEEP IN THE TREATMENT OF ACUTE DISEASE.

BY J. WALTER CARR, C.B.E., M.D.,
F.R.C.P. LOND.,

CONSULTING PHYSICIAN TO THE ROYAL FREE HOSPITAL AND
TO THE VICTORIA HOSPITAL FOR CHILDREN, CHELSEA.

AMID the constant rush of new theories and the unceasing claims of novel methods of healing some of the essentials of successful treatment may easily be overlooked, and this must be my excuse for a short note on the importance of securing adequate sleep in the treatment of disease and particularly of acute illness. Let me give an example from one of the most familiar of diseases—acute bronchitis.

A woman of 65 had been ill for about twelve days with increasing bronchitis, which had got much worse during the previous 24 hours. I saw her with Dr. J. L. Shepherd, of Friern Barret. Her temperature was about 100°F., pulse 115, respirations 36, with orthopnoea, working of the abdomen, and much inspiratory recession of the soft parts of the chest wall. Expectoration had gradually been diminishing and had now almost ceased, but abundant, large and small, moist, non-consolidating adventitious sounds were heard all over the lungs, especially at the left base. It seemed very doubtful whether she would live another 24 hours. She was treated with stimulant expectorants, vigorous counter-irritation to the chest, both front and back, and inhalations of oxygen at frequent intervals.

Two days later I saw her again, rather to my surprise, for I had not expected she would live so long. She had just held her own, but her colour was bad, sputum still very scanty, and she was obviously becoming exhausted; she said she felt worn out, for she had had only short snatches of unrefreshing sleep. The situation appeared well-nigh hopeless, left as she was. It seemed practically certain that after another sleepless night of constant, ineffective cough, heart failure would inevitably follow; on the other hand, it seemed equally certain that if she were given any drug sufficiently powerful to compel reasonably sound sleep, the secretion in her bronchial tubes would accumulate and cause fatal asphyxia.

With much hesitation we gave her by the mouth a tablet of one-fourth of a grain of morphia and one-eighth of a grain of atropine. She slept fairly soundly for several hours, but during that time her colour became worse and her respirations more and more shallow. She was kept alive by oxygen given through a tube passed directly into the nostril, which

fortunately did not interfere with her sleep. When she awoke she felt distinctly better, and began to cough more effectively. Her condition remained critical for some days longer, and the dose of morphia and atropine had to be repeated one night, but improvement, though very slow at first, was fairly continuous; she began to expectorate increasing quantities of thick, purulent sputum, and eventually made a satisfactory recovery.

A Traditional Rule Broken.

Had we not broken one of the traditional rules of medicine by giving morphia to an elderly patient with advanced general bronchitis, I believe she would inevitably have succumbed. The rule is undoubtedly excellent, but, like all others in medicine, must not be adhered to blindly, although in such desperate cases the doctor is very likely to feel that as the patient will probably die anyhow, it is better that the end should be brought about by the disease rather than by the remedies. The risk in the case described was certainly great, but less I believe than that of another sleepless, exhausting night. The morphia was given by the mouth because it seemed likely that its action, whilst equally effective, would be more gradual and therefore safer than if it were administered hypodermically. The atropine is presumably useful by diminishing the amount of secretion in the bronchial tubes and so the imminent danger of asphyxia.

In many forms of heart disease morphia as a narcotic is still more generally helpful, without the danger necessarily attendant upon its altogether exceptional use in severe cases of bronchitis. Its value in advanced cases of aortic disease, in which the patient as soon as he drops off to sleep is disturbed by sudden dyspnoea, is generally recognised. More hesitation is often felt in giving it to patients suffering from mitral disease, with a failing, irregular heart, and general oedema. The lungs are more or less waterlogged, there is probably some albuminuria, and it is naturally feared that morphia may lead to a dangerous accumulation of secretion in the bronchial tubes. Nothing of the sort need be anticipated; sound sleep is as valuable a tonic to a fibrillating heart as is digitalis; at times probably even more valuable, for the action of the digitalis or of any other cardiac tonic is likely to be more effective and more lasting if the patient can enjoy at the same time the beneficial effect of restful sleep.

The early stage of acute pneumonia affords yet another example of the oft-times beneficial effect of morphia or opium. In the later stages, especially in

it justifiable to give a brief account of the points we consider most important, omitting all theoretical speculation.

Limit Reaction and Nomenclature of Smears.

We consider as the most concise and suitable criterion for the limit reaction the disappearance of leucocytes in the vaginal smears stained by the Giemsa method—i.e., an animal that during the given observation time (see below) produces at least one smear without any leucocytes is said to have shown a positive reaction. This only occurs when the vaginal epithelium has thickened considerably, as in pro-oestrus and oestrus. Then the remaining epithelial cells in the smears gradually lose their nuclei and cornify. All intermediate stages may be seen, and in mice especially partial cornification is often the maximal reaction.

If all the cells are cornified, the symbol ++ is given; if no more than 5 per cent. of them show a nucleus the reaction is designated +. Both these reactions we call "double positive." If less than 95 per cent. but more than half the epithelial cells present are deprived of nuclei we designate it +; should less than 50 per cent. of the cells be completely cornified, the smear is characterised [+]. These two reactions we call single "positive." As the total absence of leucocytes is very rare, we include in the positive reactions those in which only a few leucocytes (but never more than 5 per cent. of the total number of cells) are present; this we indicate by adding a small - to the symbols mentioned.

All other preparations contain more than 5 per cent. of leucocytes and are termed non-positive, but here again we differentiate between the absolutely negative and those that show a certain reaction consisting of a relative increase of epithelial cells.

If more than one-third of all the cells present are epithelial this is designated by -E if most of them possess a nucleus; by -s if the majority have none. When more than two-thirds of all the cells present are epithelial and most of them have lost their nuclei, the symbol -ss is used. Smears belonging to either of these groups (-s or -ss), are considered to show an undoubted reaction.

To rule out the individual element as far as possible, all smears are examined by two trained observers independently; differences being submitted to the judgment of a third, whose opinion is final. We do not think it necessary to follow Loewe's method: exact counts of the various cell types are superfluous and practically impossible in routine standardisations.

Number of Animals.

To eliminate the individual element among the animals as far as possible, we advise the use of at least 12 for each more precise standardisation; nine animals at least should give limit (or stronger) reactions to satisfy our definition that the unit be the smallest dose which in 75 per cent. of the animals injected produces the limit reaction. Coward and Burn¹ only require 50 per cent. of limit reactions; from their curve it might be inferred that our unit is about 40 per cent. stronger than theirs, but when we standardised the same batches of hormone together the difference lay in the opposite direction. This may at first seem surprising, but the explanation probably lies in a third factor which we regard as of the utmost importance, and which Allen, Doisy, and others also recognised as essential.

Fractionation of Dose and Practical Standardisation.

The differences found by Coward and Burn (i.e., that whereas a certain dose gives positive results in one rat, ten times that dose remains inactive in another) only gain practical importance if this fractionation of the dose is omitted. They greatly depend upon the rapidity with which the hormone is eliminated; in pure aqueous solutions like our Menformon, therefore, this factor is of the utmost importance, as even a massive single dose scarcely stays long enough in the body to produce an undeniable effect. The same technique may be

responsible for the erroneous opinion that there is no difference between the doses for mice and for rats. If one dose is broken up into, say, six fractions, and these are injected at rather regular intervals within 48 hours, then the results obtained are very regular, if smears are made every morning and on the third and fourth evening after the first injection. (We always inject 0.1 c.cm. at a time.)

In one of our experiments, for instance, $\frac{3.6}{1000}$ mg. of dry substance, divided over six injections, made nine rats out of 14 react positively, while only one remained completely negative. On the contrary, out of 16 animals receiving $\frac{21.6}{1000}$ mg. at once, none became positive and only two showed a certain action. The same holds for mice, though the differences are not usually so great. The proportion of the doses with which the majority of animals show a positive reaction is as 8 to 1 and 4 to 1 in rats and mice respectively. The curve representing the percentage of animals reacting positively [doubly and singly positive (see above) together] shows a steep rise on increase of dosage, so that differences in dosage of only 10-20 per cent. are often recognisable. This holds good whether the "limit" or the "double-positive" reaction is taken as a criterion. The former has to be preferred, however, for practical purposes. Another important point that has been confirmed by many thousands of experiments is that—provided the doses are appropriately divided—a fairly accurate impression may be obtained from experiments on three mice only, and a very exact determination from a dozen or so.

When the dose has been divided into three injections, given over 24 hours, smears should be taken every morning and also on the evening of the third day, to ensure that no important reaction is missed. If, as with water-soluble preparations, the dose is given in six injections over 48 hours, then an additional smear should be taken on the fourth evening. The positive stage often persists longer when large doses are used, as may be done for qualitative tests or approximate estimations; this applies to oily preparations especially. For exact standardisations, however, frequent smears are essential, however tedious they may be, but there is no need to multiply them beyond the number given above.

Individual Variations.

Variations from fully positive to fully negative reactions may occur with the same dose. Even the same animal repeatedly injected with the same dose may show inconstant results. A point of practical importance is that now and then, though very rarely, consistently hypersensitive animals are encountered, while others never show any positive reaction even to massive doses. A series of ad hoc experiments on mice showed that body-weight may be neglected. We were also unable to detect any differences between young animals and old ones; or between those used seldom and those used very frequently. Shortly before death mice and rats often show feeble reactions, but in practice this is negligible, for these animals die very rapidly when really ill. More important are the massive subcutaneous infiltrations that sometimes occur, especially after injection of oily material, for resorption may be so slow that the reaction is very retarded.

Day factors—a shift of the general sensitiveness of all animals in the same direction on certain days—seem to play a less important rôle than with insulin or thyroxin. Yet until they are definitely excluded we think it advisable to extend every standardisation over several days, using only a few animals at a time.

Sources of error.—When standardising aqueous solutions storage bottles and syringes should never come into contact with oil as the hormone is excessively adsorbable and soluble in this material. It is best to use two separate sets of utensils of completely different appearance, the one for aqueous and the other for oily solutions.

Standard Preparation.

Standardisation of the female hormone is in reality astonishingly simple and exact if the investigator has enough collaborators and enough animals. Moreover, if the technique outlined above is strictly followed,

¹ Jour. Physiol., 1927, lxxlii. 270..

The father was Schick- and Dick-negative. He had not had scarlet fever or diphtheria. The mother, who had had scarlet fever at 4 years of age, which had left her deaf in one ear, was Schick-negative, but Dick-positive. She had not had diphtheria.

The case is of interest owing to: (1) the severity of the relapse (there is no doubt the patient would have died if antitoxin had not been given in the relapse); (2) the fact that 33 days after the relapse and 64 days after the primary attack the patient had not developed immunity; (3) that in spite of this an immunity, although it may prove to be temporary, was acquired by injections of toxoid antitoxin mixture.

Capacity to Produce Antibodies.

We would observe that the Schick and Dick tests (if positive) do not test the capacity of a person to produce antibodies when attacked by diphtheria or scarlet fever. It may be that there are three classes of individuals: (1) those with sufficient antibody-producing capacity both to survive the attack and cause immunity for a considerable period of time or permanently; (2) those with only sufficient antibody-producing capacity to survive the attack, but not to cause immunity; (3) those with not sufficient antibody-producing capacity to even survive the attack.

Adults who are Schick- or Dick-negative either: (a) have had a definite attack of the disease and been rendered immune; or (b) have possibly undergone a process of subinfection and autovaccination and been latently immunised in the manner suggested by Dudley; or (c) have a persistent hereditary immunity, which term we suggest is better than the one natural immunity generally used. On the other hand, adults who are Dick- or Schick-positive have either: (a) not been sufficiently exposed to infection, or (b) if exposed, have only had sufficient antibody-producing capacity to survive the attack and not to cause any lasting immunity. The existence of this class of persons explains the occurrence of "relapses" in diphtheria as well as in scarlet fever.

It also explains the difficulty in actively immunising certain individuals.

The view that relapses in scarlet fever are in all cases due to an implantation with a different "type" of streptococcus than the primary infecting one is a view which we think must be regarded critically. The work of F. Griffith¹ on the conversion of one "type" of pneumococcus into another shows that "types" are not permanent species and the "types" of hemolytic streptococci described in scarlet fever may prove to be even more readily interconvertible than the types of pneumococci.

No satisfactory typing of diphtheria bacilli has been adduced to explain "relapses" in that disease. We believe that in both scarlet fever and diphtheria the lack of development of active immunity in convalescence is the essential factor in the cause of the relapse.

Existence of a Class Lacking this Capacity.

The history of the case related and our experience of the lack of development of immunity in certain cases of scarlet fever suggests that there is a class of individuals in the community whose cells are incapable or only capable with difficulty of being educated to produce antitoxin and to react to a secondary stimulus. We would suggest that there is possibly a familial tendency with regard to the capacity for general and specific antitoxin production. If so, is this a Mendelian characteristic, i.e., is the capacity for the production of antitoxin in the body an inborn quality, and if so, is it transmitted to other generations? It is hoped to investigate this point if suitable cases occur.

The existence of the class of individuals deficient in antibody-producing capacity of such a capacity is a Mendelian characteristic throws some light on the scattered and varying incidence of diphtheria. If all cases of diphtheria were allowed to take a natural course, the persons who were markedly deficient

in antibody-producing capacity would not survive. Many, however, do survive because of antitoxin treatment. Hence the stock of such individuals remains and the process of natural selection which would otherwise apply is defeated.

A point of interest in the case is that although the patient failed to become immune after two consecutive attacks of diphtheria, yet she became immune after active immunisation. It is possible that the antitoxic serum had some effect in preventing the development of active immunity (as we believe occurs in some cases of scarlet fever), or it may be that the immunity now developed will only prove to be temporary, or it may be that the patient was already becoming immune and that the process was expedited by the active immunisation.

A case of scarlet fever described previously which was Dick-positive after an attack of scarlet fever and again after a "relapse" was still Dick-positive when tested three months after immunisation to a maximum dose of 5000 skin units of scarlatinal toxin.

A CASE OF EMPYEMA,

ACCOMPANIED BY OEDEMA OF THE ARM.

By NORMAN HILL, M.D., M.R.C.P. LOND.,

SENIOR ASSISTANT PHYSICIAN, BELGRAVE HOSPITAL FOR CHILDREN, AND THE METROPOLITAN HOSPITAL.

THE following case is interesting, as it illustrates a complication of empyema to which I have been unable to trace references in the literature.

A boy of 4 was admitted to the Belgrave Hospital on May 1st, 1928, complaining of cough and swelling of the left arm. He had been quite well until eight weeks before, when a cough had developed; it grew worse and the child became feverish. A doctor was called in, and diagnosed bronchopneumonia. The patient remained in bed under treatment. Two days before admission the mother noticed swelling of the left arm and the child became short of breath, a condition which grew rapidly worse up to the time of admission. He never complained of pain and never vomited. He was said to have become much thinner but his appetite was not impaired. He had had an uncomplicated attack of measles two years before, but there was no history of tuberculosis.

On examination he looked ill and was flushed and sweating. The temperature was 98°, the pulse-rate 152, and the respiration-rate 60. There was marked dyspnoea and some cyanosis. The tongue was furred but moist. Some stomatitis was present. The left side of the chest was immobile and there was marked enlargement of the veins over the upper and anterior aspect. No thrombosed axillary veins could be felt. There was no bulging of the intercostal spaces. About three inches from the middle line in the second left intercostal space was a rounded swelling, one and a half inches in diameter and raised fully half an inch above the surrounding skin. The skin over it was natural and it was not hot, tender, or pulsatile; fluctuation was present. The apex-beat was neither visible nor palpable, but the cardiac impulse could be felt in the fourth right intercostal space, two and a half inches from the right sternal border. The entire left chest was dull to percussion and the breath sounds were absent on auscultation. The area of cardiac dullness extended three inches beyond the right sternal border. There was marked oedema of the left arm, particularly below the elbow; the dorsal aspect of the hand was puffy and pitted deeply on pressure. There was no oedema of the legs or of the right arm. The abdomen was somewhat distended and the liver could be palpated two inches below the costal margin. There was no ascites. The chest was aspirated, and thick, greenish-yellow pus obtained; subsequent bacteriological examination proved this to be pneumococcal.

The hours after admission the empyema was opened under local anaesthesia by Mr. C. P. G. Winkley, an incision being made in the eighth intercostal space in the posterior axillary line. About 54 ounces of pus were evacuated and open drainage employed. The patient stood the operation well, and the wound drained freely. Within 26 hours the oedema of the arm and hand had completely disappeared and the general condition had greatly improved. Apart from a mild attack of chicken-pox which began three days after the operation, convalescence was uneventful though slow. He was discharged from hospital on August 1st looking and feeling well, but the left side of the chest was markedly retracted.

His mother was instructed to see that he carried out the breathing exercises taught him in hospital, and in October

¹ *Proc. Roy. Soc. Med.*, 1927, 20, 111. See *The Lancet*, 1928, 1, 111.

elderly people, their use is undoubtedly attended by considerable danger of respiratory failure; but certainly during the first two or three days they greatly diminish the strain upon the patient's strength by securing reasonable periods of sleep, so conserving his vitality for the trying time towards the termination of the illness and probably diminishing the chances of delirium, one of the gravest risks to life in acute pneumonia. They are, of course, particularly useful for patients in whom pain is an important factor in causing sleeplessness.

In all the above instances I have referred to the use of morphia or opium rather than one of the many milder synthetic hypnotics, of which so many have been introduced during recent years. Undoubtedly some of these are very valuable, but I am convinced that in cases of acute illness, in which fairly deep sleep lasting several hours is urgently required, none of them is so reliable or so lasting in effect as an adequate dose of morphia or opium. In our enthusiasm for new drugs we are apt to overlook the virtues of old and tried remedies.

Danger of Over-feeding.

In this connexion I may add that I believe there is a real danger of patients acutely ill being over-fed by the modern trained and qualified nurse, particularly by the night nurse. She is not taught sufficiently to realise that whilst the patient needs food by day, quiet and sleep are the essential factors to aim at by night, and that the ordinary laws of health are not suspended because a man happens to be ill. The average night nurse is only too apt to imagine she has not done her duty to her patient unless she has persuaded him to take almost, if not quite, as much food as her colleague on day duty.

Some years ago in an examination paper for senior nurses in a large London general hospital I asked the following question:—

"You are sent to nurse a man, aged 40, previously perfectly healthy, who has a sharp attack of influenza, with complete loss of appetite and a temperature of 103°. The doctor tells you to get him to take what food you can. State exactly what you would give him and at what times during the day and night."

Without a single exception the nurses said they would feed the patient every two hours both by day and by night; not one suggested that he should not be disturbed if asleep and two stated that if he would not take enough food by mouth they would feed him per rectum. Obviously these nurses had been definitely taught that because a man was ill enough to be kept in bed and had a sufficiently high temperature to be ordered fluid diet he must automatically be fed every two hours, quite irrespective of whether he might be soundly asleep, regardless of the fact that Nature was doing her utmost to indicate by loss of appetite that he would be much better without food, and that probably for many years previously, when his digestive powers were perfectly normal, he had never taken any food during the night, and that yet when he was ill, and his stomach secreting little or no gastric juice, it was to be given work to do every two hours throughout the night. I interviewed the matron of the hospital on the subject and came away with the conviction that she would have answered the question in a very similar manner to her nurses. Thus is the evil tradition perpetuated! Is it any wonder that the public generally share the conviction that directly a man is acutely ill the all-important thing is to feed him up at short intervals, so as to maintain his strength, and that the more milk and eggs he can be induced to swallow the better will it be for him? More than once I have seen real harm result from the carrying of this belief into practice; sometimes even a man's chances of recovery endangered or lost, often his discomforts increased, and his convalescence delayed. Occasionally I believe the obstinate refusal of a patient to swallow for a time anything except water has saved his life.

Truly how difficult it is for us to hit the happy mean of doing enough and not too much; we are so

easily carried off our balance by the latest enthusiasm and the most recent fad or craze, with the result that a century ago we depleted, starved, sweated, purged, and venesected our patients, half a century later for the same disease we dosed them with brandy, until (to quote the words of a cynical surgeon about a distinguished medical colleague) we "sent them into the presence of the Almighty in a beastly state of intoxication," and now we only too often pour milk and eggs into the stomachs of patients utterly unable to digest them.

A SEVERE "RELAPSE" IN A CASE OF DIPHTHERIA.

BY A. H. G. BURTON, M.D. LOND., D.P.H.,
MEDICAL OFFICER OF HEALTH, ILFORD;
AND

A. R. BALMAIN, M.B. LOND., D.P.H.,
DEPUTY MEDICAL OFFICER OF HEALTH, ILFORD.

THE text-books generally agree that a "relapse" in diphtheria occurs in about 1 per cent. of the cases. Goodall states that a relapse may be more severe than a primary attack. Both Ker and Rolleston agree that a severe relapse is uncommon. In our experience a true relapse with definite spreading membrane is an extremely rare occurrence, and this is the first occasion one of us has seen it in a series of over 1100 cases.

It is true that a number of diphtheria convalescent patients have a rise in temperature with an exudate on the tonsils which on examination can be shown to contain virulent Klebs-Löffler bacilli. We believe, however, that most of these cases are due to secondary infection and that the positive K.L.B. swab is merely due to the fact that the patient's fauces are not yet free of diphtheria organisms. The condition clears up without antitoxin treatment. An examination of seven such cases for other organisms besides K.L.B. showed pneumococci in three instances and hæmolytic streptococci in the four others. Possibly the relapse-rate of 1 per cent. quoted above includes cases of this kind.

The Case Described.

The following is an account of an undoubted severe relapse.

The patient, a female aged 19 years, was admitted in March of this year to the Ilford Isolation Hospital on the third day of a moderately severe attack of faucial diphtheria. She had a considerable amount of membrane on both tonsils: the throat swab was positive for morphological K.L.B. 40,000 units of concentrated antitoxic serum were given intramuscularly within 24 hours. Three days later her throat was clear of membrane. Thirty-one days after the primary attack the patient's temperature rose to 100° F. and she developed a little membrane on the left tonsil. The swab showed morphological K.L.B. Within 36 hours the membrane had spread to both tonsils and over the soft palate. The patient's cervical glands were much enlarged; a purulent nasal discharge was present. She was toxic in appearance and it became urgently necessary to again treat her with antitoxin. She was tested with 0.1 c.cm. antitoxin intracutaneously and showed 2 inches erythema and induration within 50 minutes. She was desensitised, commencing with 100 units of antitoxic serum and a total of 56,000 units of concentrated antitoxic serum was administered intramuscularly. The nostrils were swabbed out also with antitoxic serum.

She made a slow but uneventful recovery apart from slight palatal paralysis, and was discharged a little over ten weeks from the date of admission. Thirty-three days from the day she commenced her relapse she was Schick-tested and found to be Schick-positive. She was immunised gradually by seven increasing weekly doses of toxoid antitoxin mixture, and when tested nearly three months after the last dose was found to be Schick-negative.

She was Dick-tested and found to be Dick-negative. The family history is of some interest. The patient had previously had scarlet fever (at 6 years of age), had been 11 weeks in hospital, owing, it was said, to a "relapse." The brother, aged 13, had had two attacks of scarlet fever in one year, was Dick-negative, but Schick-positive (and was immunised with toxoid antitoxin mixture). He had not had diphtheria.

The father was Schick- and Dick-negative. He had not had scarlet fever or diphtheria. The mother, who had had scarlet fever at 4 years of age, which had left her deaf in one ear, was Schick-negative, but Dick-positive. She had not had diphtheria.

The case is of interest owing to: (1) the severity of the relapse (there is no doubt the patient would have died if antitoxin had not been given in the relapse); (2) the fact that 33 days after the relapse and 64 days after the primary attack the patient had not developed immunity; (3) that in spite of this an immunity, although it may prove to be temporary, was acquired by injections of toxoid antitoxin mixture.

Capacity to Produce Antibodies.

We would observe that the Schick and Dick tests (if positive) do not test the capacity of a person to produce antibodies when attacked by diphtheria or scarlet fever. It may be that there are three classes of individuals: (1) those with sufficient antibody-producing capacity both to survive the attack and cause immunity for a considerable period of time or permanently; (2) those with only sufficient antibody-producing capacity to survive the attack, but not to cause immunity; (3) those with not sufficient antibody-producing capacity to even survive the attack.

Adults who are Schick- or Dick-negative either: (a) have had a definite attack of the disease and been rendered immune; or (b) have possibly undergone a process of subinfection and autovaccination and been latently immunised in the manner suggested by Dudley; or (c) have a persistent hereditary immunity, which term we suggest is better than the one natural immunity generally used. On the other hand, adults who are Dick- or Schick-positive have either: (a) not been sufficiently exposed to infection, or (b) if exposed, have only had sufficient antibody-producing capacity to survive the attack and not to cause any lasting immunity. The existence of this class of persons explains the occurrence of "relapses" in diphtheria as well as in scarlet fever.

It also explains the difficulty in actively immunising certain individuals.

The view that relapses in scarlet fever are in all cases due to an implantation with a different "type" of streptococcus than the primary infecting one is a view which we think must be regarded critically. The work of F. Griffith¹ on the conversion of one "type" of pneumococcus into another shows that "types" are not permanent species and the "types" of hæmolytic streptococci described in scarlet fever may prove to be even more readily interconvertible than the types of pneumococci.

No satisfactory typing of diphtheria bacilli has been adduced to explain "relapses" in that disease. We believe that in both scarlet fever and diphtheria the lack of development of active immunity in convalescence is the essential factor in the cause of the relapse.

Existence of a Class Lacking this Capacity.

The history of the case related and our experience of the lack of development of immunity in certain cases of scarlet fever suggests that there is a class of individuals in the community whose cells are incapable or only capable with difficulty of being educated to produce antitoxin and to react to a secondary stimulus. We would suggest that there is possibly a familial tendency with regard to the capacity for general and specific antitoxin production. If so, is this a Mendelian characteristic? I.e., is the capacity for the production of antitoxin in the body an inborn quality, and if so is it transmitted to other generations? It is hoped to investigate this point if suitable cases occur.

The existence of the class of individuals deficient in antitoxin-producing capacity (if such a capacity is a Mendelian characteristic) throws some light on the epidemic and increasing incidence of diphtheria. If all cases of diphtheria were allowed to take a natural course, those persons who were markedly deficient

in antibody-producing capacity would not survive. Many, however, do survive because of antitoxin treatment. Hence the stock of such individuals remains and the process of natural selection which would otherwise apply is defeated.

A point of interest in the case is that although the patient failed to become immune after two consecutive attacks of diphtheria, yet she became immune after active immunisation. It is possible that the antitoxic serum had some effect in preventing the development of active immunity (as we believe occurs in some cases of scarlet fever), or it may be that the immunity now developed will only prove to be temporary, or it may be that the patient was already becoming immune and that the process was expedited by the active immunisation.

A case of scarlet fever described previously which was Dick-positive after an attack of scarlet fever and again after a "relapse" was still Dick-positive when tested three months after immunisation to a maximum dose of 5000 skin units of scarlatinal toxin.

A CASE OF EMPYEMA, ACCOMPANIED BY OEDEMA OF THE ARM.

By NORMAN HILL, M.D., M.R.C.P. LOND.,

SENIOR ASSISTANT PHYSICIAN, BELGRAVE HOSPITAL FOR CHILDREN,
AND THE METROPOLITAN HOSPITAL.

THE following case is interesting, as it illustrates a complication of empyema to which I have been unable to trace references in the literature.

A boy of 4 was admitted to the Belgrave Hospital on May 1st, 1928, complaining of cough and swelling of the left arm. He had been quite well until eight weeks before, when a cough had developed; it grew worse and the child became feverish. A doctor was called in, and diagnosed bronchopneumonia. The patient remained in bed under treatment. Two days before admission the mother noticed swelling of the left arm and the child became short of breath, a condition which grew rapidly worse up to the time of admission. He never complained of pain and never vomited. He was said to have become much thinner but his appetite was not impaired. He had had an uncomplicated attack of measles two years before, but there was no history of tuberculosis.

On examination he looked ill and was flushed and sweating. The temperature was 98°, the pulse-rate 152, and the respiration-rate 60. There was marked dyspnoea and some cyanosis. The tongue was furred but moist. Some stomatitis was present. The left side of the chest was immobile and there was marked enlargement of the veins over the upper and anterior aspect. No thrombosed axillary veins could be felt. There was no bulging of the intercostal spaces. About three inches from the middle line in the second left intercostal space was a rounded swelling, one and a half inches in diameter and raised fully half an inch above the surrounding skin. The skin over it was natural and it was not hot, tender, or pulsatile; fluctuation was present. The apex-beat was neither visible nor palpable, but the cardiac impulse could be felt in the fourth right intercostal space, two and a half inches from the right sternal border. The entire left chest was dull to percussion and the breath sounds were absent on auscultation. The area of cardiac dullness extended three inches beyond the right sternal border. There was marked oedema of the left arm, particularly below the elbow; the dorsal aspect of the hand was puffy and pitted deeply on pressure. There was no oedema of the legs or of the right arm. The abdomen was somewhat distended and the liver could be palpated two inches below the costal margin. There was no ascites. The chest was aspirated, and thick, greenish-yellow pus obtained; subsequent bacteriological examination proved this to be pneumococcal.

Three hours after admission the empyema was opened under local anaesthesia by Mr. C. P. G. Wakley, an incision being made in the eighth intercostal space in the posterior axillary line. About 34 ounces of pus were evacuated and open drainage employed. The patient stood the operation well, and the wound drained freely. Within 36 hours the oedema of the arm and hand had completely disappeared and the general condition had greatly improved. Apart from a mild attack of chicken-pox which began three days after the operation, convalescence was uneventful though slow. He was discharged from hospital on August 1st looking and feeling well, but the left side of the chest was markedly

His mother was instructed to see that he carried out the breathing exercises taught him in hospital, and in October

his chest appeared quite normal and symmetrical and the left lung well expanded. The X ray, except for a slight haziness at the left base due to thickened pleura, appeared to be that of a normal chest.

The chief interest of the case is the œdema of the arm, which was apparently caused by mechanical pressure on the subclavian vein impeding the venous return. Considering the comparative frequency of empyema it is surprising that this symptom does not occur more often, especially when a large amount of pus has been allowed to accumulate owing either to inadequate supervision of the patient or to failure to diagnose the condition.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

THE opening meeting of the session was held in London on Nov. 30th, when Dr. F. J. Courts gave a presidential address on

Veneral Diseases from the Epidemiological Point of View.

He said that of the evolution of the parasites of man, particularly those microscopic organisms associated with the production of disease in man, the profession was still profoundly ignorant. It was known, however, that pathogenic organisms varied in virulence, and such changes must be associated with some modifications, still obscure, in the life-history of the parasite and in its reaction to environment. Three modes of transmission of parasites of infectious diseases were known: (1) direct contagion, as in venereal diseases; (2) direct transmission by means of air, water, food, and so forth, as in influenza, pneumonic plague, cholera, small-pox; (3) indirect transmission—i.e., by an intermediate host, as in malaria. Recently there had been a revival of the idea of "epidemic constitutions," and some believed that climatic and meteorological conditions had a dominant influence. Statistical methods could not be expected to provide answers to the epidemiological problems involved. Gill had put forward a "quantum" theory—that all epidemic manifestations were essentially the outcome of loss of equilibrium between the dose of toxin and the degree of resistance, or between infection and immunity—claiming that the conclusions reached by Topley in his study of mice and by Dudley in investigating human diphtheria epidemics agreed with his theory. Gill considered that circumstances conducive to a sudden increase in the amount of infection, or infective quantum, played a predominant part in determining epidemic explosions.

In connexion with venereal diseases some of the characteristics of more typical epidemic diseases were found—namely, wave form, variations in virulence, seasonal incidence, special incidence upon certain age-groups. Syphilis, however, was much more chronic than the usual epidemic diseases, hence it was to be expected that the wave periods would be slow and lengthened out. The President was certain that at times syphilis occurred in epidemic form, the most remarkable instance being the outbreak at the end of the fifteenth century, which by many was confused with leprosy and on which he dwelt at some length. Incidentally he was unable to agree with the view that syphilis was introduced to Europe by Columbus and his sailors on their return from America. It most probably existed in Europe and Asia long before, and descriptions of it occurred in Chinese literature of 2000 B.C., and in a Japanese book of the ninth century. Several writers considered that the plague of Baal-peor, in which 24,000 Israelites perished, was syphilis. The large-scale epidemic of syphilis in this country at the end of the fifteenth century was not regarded by temporary physicians as in essence venereal, as

there were so many extragenital chancres, but this was explicable by the lack of personal cleanliness, the promiscuous sharing of beds and of drinking vessels without cleaning. There was some increase in syphilis in England after the South African War, also after the late war, but no indications of a very severe type of infection. After the late war the increase in syphilis seemed to have been greater in Russia than elsewhere; Dr. Courts quoted figures from that country. The antiquity of gonorrhœa was generally well recognised; it was the "running issue" described in Leviticus XV., and Moses enjoined scrupulous cleanliness as a precaution against infection. Dr. Courts was not aware of any records of great epidemics of gonorrhœa, nor even of local outbreaks of a highly virulent type.

Discussing the problem of immunity in a general way, he said that recent work cast some doubt on whether the phenomena observed could be fully explained by natural immunity in a section of the population along with acquired immunity in those who had had the disease and survived. In connexion with syphilis the problem of immunity was particularly puzzling. No worker had succeeded in producing active immunity to syphilis, either in man, monkeys or rabbits. Lesions had been produced, by inoculation identical with those of spontaneous syphilis in patients already suffering from syphilis in various stages. Topley's work suggested that latency was very important in relation to infectious disease, and that it might have an important bearing on individual and communal immunity. Women who had never presented clinical signs of syphilis might yet give birth to syphilitic infants, and their Wassermann reaction might be positive.

Looking to the future, the President said there was hope that a vaccine would one day be discovered which would reach the gonococcus in its lair and destroy it. In the case of syphilis the foe seemed even more resourceful than the gonococcus. Arsenobenzol preparations had dealt the *Spirochaeta pallida* a shrewd blow, but it appeared that certain strains of the organism were being evolved which were capable of considerable resistance to arsenic. He had hopes that by careful study of all aspects of the problem and perseverance there would come as a reward the final mastery of this scourge of humanity.

Discussion.

Colonel L. W. HARRISON quoted a remark of the President that in some countries syphilis among the natives was mild in degree, but when immigrants to the country were attacked, it was severe. He thought the different points of view could be reconciled by assuming the existence of different strains of the germ of syphilis. Experimental research gave some support to this idea. For example, if a rabbit received an inoculation of one strain, and a chancre and orchitis ensued, then after 90 days the disease was eradicated by arsenobenzol treatment; in spite of that animal having been cured, one could not cause a fresh chancre by injecting the same strain. If, however, a different strain were inoculated, then a fresh chancre resulted. The sailors returning from America with the spirochete into Spain, and the visitation so generated may have had all the virulence of a new disease on virgin soil. One authority had suggested that syphilis had to be in a community for from six to ten generations before it began to affect the central nervous system, as in the production of general paralysis, and that after lasting a certain length of time, G.P.I. declined. In this country general paralysis began suddenly to decline in 1919, and the drop had gone on steadily until now. The President's point as to the latency of symptoms being coupled with the capacity to transmit syphilis to others was confirmed by experiments on mice. The *Spirochaeta pallida* was inoculated into mice, and their brains became virulent for other mice, and yet the brains of the first showed no histological signs of reaction to the spirochete. The question of resistant and non-resistant strains might well be

rather one of changes in the tissues. In some patients the disease resisted the usual remedies, but a medicine which brought about a change in metabolism enabled the patient to make use of the antisyphilitic injections. One particular patient in the speaker's experience was continually relapsing; then he was given a dose of thyroid gland, and thereafter it became a tractable case, the same remedy being used throughout.

Dr. HARDY KINGSTON spoke of a visit to China, where he found that if a European contracted syphilis he had it in a much more severe form than did Chinamen. In Russia extragenital syphilis was very common, and over 90 per cent. of the population of some rural districts suffered from the disease.

Dr. E. T. BURKE said it was of considerable interest to settle the question of the date of the origin of syphilis in Europe, as the time factor was of importance in studying the subject. His view was that it originated in the New World, and was unknown in Europe until it was brought thence by the sailors with Columbus. Nothing appeared in records concerning congenital syphilis in Europe prior to 1493. He agreed with what had been said as to syphilis showing a greater severity in immigrants to a country than in natives. During the late war if a soldier serving in the East, as on the frontiers of Persia, acquired syphilis, usually it was of more virulent type than that seen in the inhabitants. And much the same sort of thing occurred during the Peninsular War.

Major A. DAWSON said there was an impression that a large number of the people of Trinidad were suffering from syphilis, but Dr. Wilson, the senior medical officer there on the civil side, said much of the prevailing sickness was due to yaws, which could be regarded as a near cousin to syphilis. It was of some importance to know whether having one of those diseases prevented the development of the other.

Dr. DOROTHY LOGAN suggested that perhaps strange climatic and living conditions in the case of the immigrant might account for the observed increased virulence.

The PRESIDENT replied. He said that the introduction into a community of a fresh strain of spirochæte might lead to a virulent type of the disease. His own idea of the action of arsenobenzol was, not that it killed the spirochæte directly, but that it so modified the body tissues that they were able to deal with the parasite. Climate and environment should not be omitted when considering the factors concerned in the continuance of syphilis and other venereal diseases.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF OBSTETRICS.

A MEETING of this Section was held on Nov. 23rd, with Dr. GIBBON FITZGIBBON, the President, in the chair.

Carcinoma of the Cervix: Treatment with Radium.

Dr. BETHEL SOLOMONS exhibited a specimen of carcinoma of the cervix, removed by the Wertheim method.

The patient, aged 36, was a 5-para, whose last baby was 11 months old. Two months after the birth menstruation returned and she had bled almost continuously for nine months when she came to the Rotunda Hospital. The growth was very extensive locally, but did not appear to involve either parametria, bladder, or rectum. The operation and recovery were without incident. Dr. F. S. K. Bourke reported that the specimen was "a solid carcinoma originating from the squamous epithelium of middle maturity. The tumour has infiltrated the cervix, but the proliferation is more external than internal." The measurement of a half-section of the growth after removal was 4.5 c.cm.

Dr. Solomons dwelt on the fact that radical operation was the choice for a case of this type—i.e., a growth freely movable and of great magnitude. A large quantity of radium would be required for treatment of such an extensive growth. He gave X rays as a routine after operation.

Dr. D. G. MAMILL, referring to the fact that the patient's last confinement had taken place only nine

months before the finding of the tumour, asked if there had been any history of difficulty at the confinement, and said he did not think the tumour could have reached its present magnitude in nine months. He thought it probable that there must have been some evidence of malignancy at the confinement.

Prof. A. H. DAVIDSON said he thought it was time that an authoritative statement on the present position of radium and operation in cases of cancer of the cervix was issued. He had seen a great many inoperable cases which had been treated by radium in which the results had not been satisfactory, and could only remember one inoperable case which had been treated about four years previously, in which there had been no recurrence.

Dr. R. M. CORBET said he thought if carcinoma was found soon after confinement the prognosis was favourable, as this meant it was found in an early stage. He referred to a patient of his who had had a normal delivery in July, 1925, and who in December, 1926, had been sent to him again with a diagnosis of incomplete abortion. He had found a malignant condition, done a Wertheim operation, and the patient had been perfectly well since.

Dr. SOLOMONS, in reply, said that the patient was confined in the country 11 months previously, and he was informed there was no difficulty in the labour. He agreed with Dr. Corbet that a tumour discovered apparently soon after confinement probably meant a favourable prognosis. He did not believe that sarcoma was likely to be found in the microscopic sections. It was extremely difficult to estimate the relative efficiency of radium therapy and operation for carcinoma of the cervix. In both success depended on the skill of the operator. Heyman, of Stockholm, was getting excellent results with radium which he used in all cases; his technique was beautiful. It was difficult for men who had not a large quantity of radium, and who had not the experience necessary to obtain the best technique, to compare their results with those of Heyman and others. The same remark applied to the operation. The Wertheim operation was difficult, and the best results were obtained by the man with the largest experience. He (Dr. Solomons) advocated operation for operable cases, and he used radium for the other types. In the latter, working with Dr. Stevenson, he had had some striking improvements. It was an easy matter to pick out the authoritative papers on operation and radium therapy from the others.

Dr. SOLOMONS also showed a specimen of

A Large Fibroid.

The patient was aged 33, and had been married for one year. There had been no previous pregnancy, but amenorrhœa had continued for five months, with some slight abdominal pain. On examination a soft tumour, obviously a five months' pregnancy, was found in the lower abdomen; separated from it by a slight groove, and filling the whole of the rest of the abdomen, was a large hard somewhat regular tumour. This was freely mobile and slightly resonant on percussion. A radiogram confirmed the diagnosis of pregnancy. The spleen shadow was visible, and there seemed to be a slight connexion between the pregnant uterus and the tumour. The differential diagnosis lay between an enlarged spleen, a mesenteric tumour, and a large fibroid or an ovarian tumour. A blood count showed the red cells 3,330,000; hæmoglobin 60 per cent.; colour-index 0.9. On opening the abdomen it was obvious that the swelling was a fibroid; it filled most of the available space in the abdomen. Having been delivered, it was removed from the left cornu of the pregnant uterus and the cavity stitched. There were four other fibroids in the uterus, one of which was removed; there was very alarming hæmorrhage from the bed of this tumour which seemed to be over the placental site; the hæmorrhage was controlled by suture. It did not seem advisable to remove any of the other tumours, as they would not interfere with the pregnancy which was still progressing.

The PRESIDENT agreed with Dr. Solomons that the only treatment in this case was removal of the tumour. He thought the prognosis was good. He was specially interested in the diagnosis of this case, because he had recently seen at Mercer's Hospital a somewhat similar one. The patient had a fairly large

his chest appeared quite normal and symmetrical and the left lung well expanded. The X ray, except for a slight haziness at the left base due to thickened pleura, appeared to be that of a normal chest.

The chief interest of the case is the cedema of the arm, which was apparently caused by mechanical pressure on the subclavian vein impeding the venous return. Considering the comparative frequency of empyema it is surprising that this symptom does not occur more often, especially when a large amount of pus has been allowed to accumulate owing either to inadequate supervision of the patient or to failure to diagnose the condition.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

THE opening meeting of the session was held in London on Nov. 30th, when Dr. F. J. COUTTS gave a presidential address on

Venereal Diseases from the Epidemiological Point of View.

He said that of the evolution of the parasites of man, particularly those microscopic organisms associated with the production of disease in man, the profession was still profoundly ignorant. It was known, however, that pathogenic organisms varied in virulence, and such changes must be associated with some modifications, still obscure, in the life-history of the parasite and in its reaction to environment. Three modes of transmission of parasites of infectious diseases were known: (1) direct contagion, as in venereal diseases; (2) direct transmission by means of air, water, food, and so forth, as in influenza, pneumonic plague, cholera, small-pox; (3) indirect transmission—i.e., by an intermediate host, as in malaria. Recently there had been a revival of the idea of "epidemic constitutions," and some believed that climatic and meteorological conditions had a dominant influence. Statistical methods could not be expected to provide answers to the epidemiological problems involved. Gill had put forward a "quantum" theory—that all epidemic manifestations were essentially the outcome of loss of equilibrium between the dose of toxin and the degree of resistance, or between infection and immunity—claiming that the conclusions reached by Topley in his study of mice and by Dudley in investigating human diphtheria epidemics agreed with his theory. Gill considered that circumstances conducive to a sudden increase in the amount of infection, or infective quantum, played a predominant part in determining epidemic explosions.

In connexion with venereal diseases some of the characteristics of more typical epidemic diseases were found—namely, wave form, variations in virulence, seasonal incidence, special incidence upon certain age-groups. Syphilis, however, was much more chronic than the usual epidemic diseases, hence it was to be expected that the wave periods would be slow and lengthened out. The President was certain that at times syphilis occurred in epidemic form, the most remarkable instance being the outbreak at the end of the fifteenth century, which by many was confused with leprosy and on which he dwelt at some length. Incidentally he was unable to agree with the view that syphilis was introduced to Europe by Columbus and his sailors on their return from America. It most probably existed in Europe and Asia long before, and descriptions of it occurred in Chinese literature of 2000 B.C., and in a Japanese book of the ninth century. Several writers considered that the plague of Baal-peor, in which 24,000 Israelites perished, was syphilis. The large-scale epidemic of syphilis in this country at the end of the fifteenth century was not regarded by temporary physicians as in essence venereal, as

there were so many extragenital chancres, but this was explicable by the lack of personal cleanliness, the promiscuous sharing of beds and of drinking vessels without cleaning. There was some increase in syphilis in England after the South African War, also after the late war, but no indications of a very severe type of infection. After the late war the increase in syphilis seemed to have been greater in Russia than elsewhere; Dr. Coutts quoted figures from that country. The antiquity of gonorrhoea was generally well recognised; it was the "running issue" described in Leviticus XV., and Moses enjoined scrupulous cleanliness as a precaution against infection. Dr. Coutts was not aware of any records of great epidemics of gonorrhoea, nor even of local outbreaks of a highly virulent type.

Discussing the problem of immunity in a general way, he said that recent work cast some doubt on whether the phenomena observed could be fully explained by natural immunity in a section of the population along with acquired immunity in those who had had the disease and survived. In connexion with syphilis the problem of immunity was particularly puzzling. No worker had succeeded in producing active immunity to syphilis, either in man, monkeys, or rabbits. Lesions had been produced, by inoculation, identical with those of spontaneous syphilis in patients already suffering from syphilis in various stages. Topley's work suggested that latency was very important in relation to infectious disease, and that it might have an important bearing on individual and communal immunity. Women who had never presented clinical signs of syphilis might yet give birth to syphilitic infants, and their Wassermann reaction might be positive.

Looking to the future, the President said there was hope that a vaccine would one day be discovered which would reach the gonococcus in its lair and destroy it. In the case of syphilis the foe seemed even more resourceful than the gonococcus. Arsenobenzol preparations had dealt the *Spirochaeta pallida* a shrewd blow, but it appeared that certain strains of the organism were being evolved which were capable of considerable resistance to arsenic. He had hopes that by careful study of all aspects of the problem and perseverance there would come as a reward the final mastery of this scourge of humanity.

Discussion.

Colonel L. W. HARRISON quoted a remark of the President that in some countries syphilis among the natives was mild in degree, but when immigrants to the country were attacked, it was severe. He thought the different points of view could be reconciled by assuming the existence of different strains of the germ of syphilis. Experimental research gave some support to this idea. For example, if a rabbit received an inoculation of one strain, and a chancre and orchitis ensued, then after 90 days the disease was eradicated by arsenobenzol treatment; in spite of that animal having been cured, one could not cause a fresh chancre by injecting the same strain. If, however, a different strain were inoculated, then a fresh chancre resulted. The sailors returning from America with Columbus may have brought back a new strain of spirochaete into Spain, and the visitation so generated may have had all the virulence of a new disease on virgin soil. One authority had suggested that syphilis had to be in a community for from six to ten generations before it began to affect the central nervous system, as in the production of general paralysis, and that after lasting a certain length of time, G.P.I. declined. In this country general paralysis began suddenly to decline in 1919, and the drop had gone on steadily until now. The President's point as to the latency of symptoms being coupled with the capacity to transmit syphilis to others was confirmed by experiments on mice. The *Spirochaeta pallida* was inoculated into mice, and their brains became virulent for other mice, and yet the brains of the first showed no histological signs of reaction to the spirochaete. The question of resistant and non-resistant strains might well be

Shaw gave the classical characters of decidual formation as the presence of decidual cells together with round cells in a fibrillated matrix.

The decidual cell was normally and properly found in the endometrium where it was derived from the stromal cell, and it could be demonstrated in the premenstrual phase of menstruation and in uterine and extra uterine pregnancies. Its distribution, however, was much wider than this, for it had been found in the muscle wall of the uterus, the cervix, Fallopian tubes, ovaries, pelvic peritoneum, appendix, omentum, and various other organs (ectopic decidual cells). This distribution closely resembled that of endometrioma, and if one accepted Sampson's theory as to the causation of these tumours one was tempted to ask if the ectopic decidual cells had any relation to them. Wilfred Shaw did not accept Sampson's views on endometrioma, and explained the distribution by suggesting that the property of decidual formation was not inherent in all cells, but only in those derived from the subcœlomic connective tissue. In true cases of endometrioma, whether in the uterus, rectovaginal space, or ovaries, a decidual reaction could generally be demonstrated during pregnancy.

The occurrence of decidual formation in the ovary was stated to be very constant during pregnancy, whether the latter be uterine or extra-uterine, and Wilfred Shaw and others had found a similar change during menstruation. The cells were arranged usually in groups in the connective tissue of the tunica albuginea, and formed either nodules projecting from the surface of the ovary or flattish areas. More rarely the cells were found deep in the cortical stroma. In the case of ovarian pregnancy which he had described there was a very well-marked nodule of decidual cells immediately under the surface of the ovary. It was formerly supposed that decidual cells were produced through the local stimulus of the embedded ovum, but this view was untenable at the present time, for it was now realised that the decidua of pregnancy was merely a further development of the decidua found during the pre-menstrual phase, and was developed whether the ovum was in the uterine cavity or elsewhere. As a matter of fact, pregnancy was not necessary for the formation of a decidua at all, for Loeb was able to produce this structure in rabbits during pseudo-pregnancy by injuring the lining of the uterine cavity. This observer's experiments appeared to show that the primary factor in the formation of the uterine decidua was the presence in the circulating body fluids of a hormone developed in the corpus luteum. This hormone sensitised the uterine mucosa and other cells which then formed a decidua in response to any non-specific irritation.

The PRESIDENT described the occurrence of islands of decidual tissue on the peritoneal surface of the utero-vesical reflexion. He showed microscopical sections of such an island which, though easily removed by light pressure, left a raw, bleeding surface behind.

Mr. W. W. KING (Sheffield) said that he had excised one of these rusty-looking ovaries at a Cesarean section about the time of the publication of Wilfred Shaw's paper, and had found decidual cells both on the surface and in the substance. The latter were of special interest, as they appeared to be either a decidual change in the connective tissue cells of an old corpus luteum or a metaplasia of the lutein cells themselves into decidual cells. He showed slides illustrating the presence of the decidual cells arising in the corpus luteum, but confessed that he was unable to determine from which type of cell they arose. He had seen similar rusty-looking ovaries in the course of operations upon fibroids, but on section the only showed connective tissue and mesothelial cells derived from the peritoneum.

Prof. DONALD also reported a case of ovarian pregnancy and two cases of red degeneration in fibroids; Dr. E. A. GRIMMARD (Manchester) described a case of rupture of the uterus; Mr. KING spoke on the formation of an artificial vagina; Dr. K. V. BAILEY gave

an account of a case of melanotic sarcoma of the vagina with secondary deposits in the inguinal glands; and Prof. DONALD showed specimens of uterus subseptus and carcinoma of the cervix and body of the uterus.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ORTHOPÆDICS.

At a meeting of this Section on Dec. 4th the chair was taken by Mr. NAUGHTON DUNN, the President, and a discussion on the

PAINFUL SHOULDER

was opened by Mr. GEORGE PERKINS. The term, he said, conjured up the vision of a more or less constant clinical syndrome, though the pathology was to many hazy and the treatment often empirical. He excluded "shoulder-tip" pain, which had few mysteries and might occur whenever the phrenic nerve was irritated. Of the painful shoulder proper the symptom was pain, usually felt a few inches above the insertion of the deltoid and often continued down the outer side of the arm as far as the hand. There was little or no muscle wasting, no reaction of degeneration, no alteration in sensation or the reflexes, and no tenderness of the main nerve-trunks. Movements increased the pain and the weight of the arm caused a constant ache in the limb. Four types might be disentangled from the medley: (1) adhesions, (2) tendonitis, (3) osteoarthritis, and (4) subacute arthritis.

Adhesions round the capsule often followed trauma passing up the arm and spraining the shoulder-joint in its course. Hemorrhage caused scar tissue, and the patient complained of stiffness of the shoulder and pain on movement. Some or all movements were limited, particularly rotation and abduction, but only in the outer half of their range. The inner half was painless and free of spasm. This type was preventable and curable. The shoulder-joint should be kept mobile after falls on the hand, whether or not it seemed to have been damaged. If adhesions were allowed to form they could be broken down under anaesthesia. It was preferable to mobilise repeatedly in stages under nitrous oxide anaesthesia, so that the patient could begin active movements immediately. Physiotherapy without manipulation was valueless.

The symptoms of tendonitis had been described by Codman in 1906 under the title of "subdeltoid bursa"—a term which was not consistent with the pathology. Often after unusual exertion, often spontaneously, severe pain began over the outer side of the lower half of the deltoid, sometimes also round the external epicondyle and down the hand, varying in intensity and worse at night. There was a tender spot over the greater tuberosity of the humerus which disappeared on abduction of the arm. There was no swelling or heat. Movement was full, but painful through a small arc, from about 75°-90° of abduction with the shoulder slightly forward and slightly internally rotated. The disability varied enormously. Most often it was merely a nuisance; the patient forgot his shoulder until he reached the painful arc and then broke off his movement and might drop things. If he avoided the movements causing pain the condition quieted down in a few days or weeks, only to recur on undue exertion. Occasionally the attack might be so severe as to suggest fracture and require morphia. The shoulder muscles did not go into protective spasm. Suggested aetiological factors included bursitis and calcareous deposits beneath the bursa in the tendon of the supraspinatus. In Mr. Perkins's opinion these were seldom seen, but roughness of the greater tuberosity was common. Moschowitz had concluded that the cause was tendonitis, small areas of tendon undergoing necrosis and calcareous degeneration after trauma. It was plausible to explain the pain as due to the humeral head impinging on the beak of the acromion process, and bursitis would prevent this impact. Sepsis was not an important aetiological factor. Every conceivable form of treatment had been

tumour filling the middle of the abdomen which at first suggested a spleen, but the blood count negatived this. The abdomen was opened and a malignant growth of the mesentery was found.

Prof. A. H. DAVIDSON showed a specimen of

Myomatous Uterus with Amputated Fallopian Tube.

The patient, aged 50, complained of irregular and heavy uterine hæmorrhage for the past six months. She had been married for 26 years and had no children or miscarriages, and her menstrual periods had been regular up to six months ago. A fibrous polypus was found protruding from the cervical canal and a multinodular fibroid uterus. In view of her age Prof. Davidson decided to perform hysterectomy. At operation a peculiar and interesting condition of the right tube was found. There was a complete amputation of the tube at the inner end of the isthmal portion, and there was a thin fibrous cord running from that point to a cystic enlargement filled with caseous material, adherent to and embedded in a portion of the omentum. It seemed as if the tube had become parasitic on the omentum. The left tube, the seat of old-standing salpingitis, was disorganised. A hysterectomy and double salpingo-oophorectomy was performed. Dr. F. S. Bourke, who examined the tube, reported as follows: "A section of the peduncle attached to the large caseous mass, consists of a fibromuscular structure resembling in arrangement the muscle wall of the Fallopian tube. There is no evidence, however, of any epithelial lining. I am unable to say definitely that this is an amputated tube, but it seems the most likely explanation for its occurrence in such a situation. Smears of the caseous matters were examined, but no tubercle bacilli were found."

The PRESIDENT thought that this was an amputated tube, as the lumen of the tube was filled with caseous material.

Dr. NINTAN FALKINER thought that it was a caseous gland. As a rule the caseous mass was in the upper part of the tube, and in this case it had been in the omentum which he regarded as being rather against the condition being an amputated tube.

Dr. W. H. ASHMORE reported a case of Puerperal Septicæmia.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

At a meeting of this Society, held in Manchester on Oct. 26th, with Mr. LEITH MURRAY (Liverpool), the President, in the chair, a case of

Sarcoma of the Uterus

was described by Prof. DANIEL DOUGAL (Manchester).

The patient was 58 and had been married 33 years. She had borne one child 25 years previously. Fourteen years ago one breast had been removed for carcinoma, and three years later a similar growth was removed from the opposite breast. The menopause occurred at 55, and after this there were one or two irregular periods, and then nothing was seen until about seven months before operation. During this period of seven months she had had a constant blood-stained and yellowish discharge. She complained of no pain, the discharge being the only trouble and the one for which she sought medical advice. Her general health had not been good for six months.

On examination the uterus was much enlarged and formed a firm uniform tumour reaching almost to the umbilicus. A diagnosis was made of carcinoma of the body of the uterus or carcinoma with fibroids, and she was admitted immediately to hospital. She was operated upon on Feb. 11th, 1928, and the uterus was removed with both appendages. One or two enlarged glands were also removed from the iliac groups. The uterus was about the size of a five months' pregnancy, and contained a large necrotic growth in its cavity. There were also one or two small fibroids. The hysterectomy was perfectly straightforward, and the patient made an uneventful recovery and went home at the end of three weeks.

The uterus measured 7 inches in length, 5 inches in width, and 1 inch antero-posteriorly. There was a fibroid about the size of a walnut low down on the right side, and one or two smaller fibroids elsewhere in the wall of the uterus. The enlargement of the uterus was due to a large necrotic tumour which filled the cavity and showed areas of hæmorrhage. Microscopic examination showed the growth to be a round-celled sarcoma, so presumably it originated in the endometrium.

Three months after discharge from hospital the patient complained of severe sciatica in her right leg. On examination Prof. Dougal found a definite fixed swelling in the right side of the pelvis, and advised that there was nothing more to be done except to relieve her pain. However, as her own doctor was anxious that some further treatment should be tried, she was readmitted, and Dr. G. E. Birkett applied radium by needles inserted into the right vaginal fornix. This treatment did not improve matters, for within four weeks she had become so ill that she had lost the use of her lower limbs. She was admitted to the Christie Hospital, where she died in about a fortnight's time, four months after the uterus was removed.

Dr. C. POWELL WHITE made a *post-mortem examination*, and reported: "There is a recurrent mass of growth occupying the pelvis and infiltrating the vagina and bladder, giving rise to acute cystitis. The growth has extended along the walls of the pelvis behind the rectum, but the latter is not infiltrated. The growth has involved the upper part of the sacrum and the adjacent portions of the ileum on both sides, and has invaded the spinal canal producing compression of all the roots of the cauda equina. There are no enlarged glands and no metastases. The sites of operation in both breasts are quite sound. Microscopically the growth is a small round-celled sarcoma, and is infiltrating the bladder, muscle walls, nerves, and bones."

In his own experience, said Prof. Dougal, sarcoma was a very rare tumour. He had only seen four of them during the last three years. The majority of the patients had been elderly women, past the menopause. A point of interest in the present case was the extraordinary infiltrating power of the tumour which had largely destroyed the sacrum and lower part of the spinal cord.

Dr. C. P. BRENTNALL (Manchester) showed a specimen of sarcoma of the uterus. He pointed out that the growth was largely submucous, apparently in process of becoming polypoid, although in places it reached almost to the peritoneal surface of the uterus. It was nowhere encapsulated, but macroscopically it was of the circumscribed variety. He thought it was a primary sarcoma of the uterine muscle, arising as such *de novo*, and not in a pre-existing fibroid. In the fresh state the tumour was soft and the cut surface presented a yellow and lobulated appearance. There was no hæmorrhage into the tumour, nor evidence of gross necrosis or formation of cystic spaces such as was described as occurring in these tumours. Sections of the tumour showed it to be composed of solid masses of small round cells. There was nothing to suggest a fibromyoma. The patient was alive and well two years after operation.

Prof. ARCHIBALD DONALD (Manchester) discussed the diagnosis of sarcomata, and the PRESIDENT commented on the extreme malignancy of the tumours in his experience.

Prof. DOUGAL also read a note on

Decidual Formation in the Ovary during Pregnancy.

He said that when performing Caesarean section or some other operation on the pregnant uterus he had often been struck by the peculiar appearance of the ovaries. The outer surfaces were streaked or mottled with a reddish-brown material, and this on microscopic examination was seen to be composed of irregular outgrowths of connective tissue apparently derived from the tunica albuginea. The cells of this tissue frequently showed a decidual reaction. The ovary which he was now showing was removed along with a three months gravid uterus from a woman with severe mitral stenosis in whom it was considered advisable to terminate the pregnancy and perform some sterilising operation at the same time. Both ovaries from this case showed the streaked appearance he had described, but in this particular one the condition was more marked and almost resembled a papillary growth. Its appearance on microscopic examination was that of typical decidua. The decidual cell was generally described as being large and oval with faintly granular and vacuolated protoplasm and a prominent nucleus. Both nucleus and protoplasm stained faintly with the usual reagents. The cells themselves lay in a fibrillar matrix, and around them were numbers of small round cells. Wilfred

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1927 statistics of two English towns and three English boroughs, all of county borough status:—

Name of town and estimated (1927) population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Diarrhoea, &c., under 2 years.	Maternal mortality from childbirth.
Liverpool (856,266)	22.2	13.9	1.38	1.14	3.6	1.1	94/31	18.4	4.4
Birkenhead (158,500)	18.2	12.6	1.28	1.34	2.5	1.7	95/35	21.9	2.1
Preston (127,100)	14.9	14.0	0.97	1.31	3.4	2.0	109/46	5.8	4.7
Norwich (124,600)	17.1	12.2	1.08	1.53	2.1	1.5	63/29	5.6	1.4
Rotherham (70,080)	20.8	13.5	1.17	1.21	3.2	1.3	90/36	6.8	2.7

The young child (1-5) mortality-rate per 1000 births was: Liverpool, 63; Birkenhead, 37; Preston, 64; Norwich, 36; and Rotherham, 65.

Liverpool.

Dr. A. A. Mussen reports that the infant mortality-rate (91) was the lowest yet recorded, and that the prevalence of influenza, which caused such a large number of deaths among adults, did not apparently affect the infants to any serious extent. There were 350 deaths of children under 2 years from diarrhoea and enteritis, and a special investigation into this subject is described. About three-quarters of these deaths are of the acute infective disease, which is steadily falling, leaving a residuum of deaths where the fatal result is due to other causes. The infective disease chiefly affects the central portion of the city, and in nearly half of the fatal cases the child is found to be definitely unhealthy or suffering from lack of parental care before the onset of diarrhoea. Over 80 per cent. of the deaths from diarrhoea and enteritis occur in the first year of life, and breast-feeding is a real protection against the disease. The death-rate from tuberculosis, although high, was the lowest ever recorded in Liverpool. A striking feature of the statistics is the increasing number of deaths and births which take place in institutions. Thus out of a total of 11,874 deaths of Liverpool residents, 5240 took place in public institutions; and during 1927 3523 of the 19,020 births took place in institutions, whilst in 1923 the corresponding figures were 2138 out of a total of 20,695.

The difficulties with regard to housing are still considerable. No closing orders were made during the years 1922 to 1927 (inclusive). Letters were addressed to the owners of 900 scattered insanitary houses, asking for their proposals thereto. Replies were received, but no definite action has been taken owing to the difficulty of providing accommodation for the rehoused. Nine condemned areas are waiting to be dealt with. A central area scheme, covering about 5.6 acres—involving 2876 inhabitants and 431 dwellings—is under the consideration of the Ministry. It is proposed to provide five blocks, including 408 dwellings, 28 with one bedroom, 95 with two bedrooms, and 285 with three bedrooms, at a total estimated cost of £261,500. Up to the present the corporation have provided, since 1869, 3061 tenements in the old city area; and since 1919 they have erected in the suburbs 15,748 houses and 169 flats, while 1257 other houses are in progress. The rentals of the corporation

tenements vary from 2s. 8½d. to 12s. 6d., and of the self-contained cottages from 8s. 11½d. to 10s. 7½d. per week.

There were eight confirmed cases of anthrax and one death among workers who handled foreign wool, hair, or hides. Sixty-nine new cases of encephalitis were reported with 16 deaths. Nine additional deaths occurred of persons notified in previous years. The death-rate from respiratory diseases, including influenza, which has always been high in Liverpool, during the last seven years was only two-thirds of what it was in 1871 to 1900.

Liverpool has 25 prematernity clinics held weekly. 14 under the auspices of the Maternity Hospital, two at the Royal Infirmary, two by the Child Welfare Association, and seven by the Health Committee. The last-named were attended by 2288 new cases. The wards of the Carnegie centre admitted 109 babies, 43 for lack of normal progress, 20 for infantile dyspepsia, 14 for early rickets, and 32 for observation. Six babies were supervised for breast-feeding, the mothers attending at stated intervals during the day. On five occasions the milk supplied to the hospitals for cooking was found to be tuberculous, and on one occasion the milk supplied to the infant welfare centres. Since Jan. 1st, 1928, the infant welfare centres have been supplied with Grade A (T.T.) milk. The seamen's V.D. dispensary, with a whole-time medical officer, is much appreciated, and the new V.D. cases there have increased from 1077 in 1925 to 1547 in 1927.

Birkenhead.

Dr. D. Morley Mathieson reports that before the Extension Bill Birkenhead had a density per acre of 37.2, and that only ten of the 82 county boroughs of England and Wales had higher densities at the last census. The Bill operates from April 1st, 1928, and adds 2092 acres, on the western fringe, with a population of 2751. The rainfall at Bidston was about 7½ in. above the average of the last 61 years. Of 33 samples of milk examined for tubercle, seven gave a positive result. All the samples were ordinary milk, except one Grade A., the circumstances of which were interesting. A calf, killed at the abattoir, had extensive tuberculosis, and was ascertained to be from an outside farm supplying Grade A milk. On following up it was found that of 77 cows on the farm one had tuberculosis of the udder and another pulmonary tuberculosis, thus indicating that quarterly inspection by a veterinary surgeon is not an absolute safeguard. In the case of the other tuberculous milk samples a tuberculous cow on the farm was found in every case but one. In 15 cases proceedings were taken against vendors of dirty milk, and in all cases successfully.

At the end of the year there were 2080 cases on the tuberculosis register, more than ten times the average number of annual deaths. Of 398 contacts examined five were found to be suffering from respiratory and two from "other" tuberculosis, while 21 were classed as "suspect." Artificial sunlight has been introduced at Thingwall Sanatorium. Dr. Mathieson reports: "On the whole our experience has been that artificial sunlight, judiciously and carefully employed, has proved its worth. But it must not be thought to compare in efficacy with natural sunlight." At the V.D. clinics 100 per cent. increase in the new female gonorrhoea cases is regarded as a satisfactory feature. There were seven cases of encephalitis lethargica notified, five of which ended fatally. Immunisation against diphtheria is offered at the infant welfare clinics, and at the end of the year 176 children had received the full course. The staff at the hospital and patients suffering from other diseases are immunised against diphtheria. A child admitted during 1927 with severe diphtheria was one for whom immunisation was refused in the previous year. The antenatal clinic was attended by 85 women in their first pregnancy and by 309 in a second or subsequent pregnancy. A satisfactory feature was the increased attendance of primigravidae. The total births numbered 2870.

tried and symptoms disappeared in time with or without treatment. In the ordinary subacute type it was sufficient to avoid all painful movements. For the acute type many surgeons had had success from removal of the calcareous deposit (Carnett's operation). The only alternative to operation was complete fixation in mild abduction or hyperabduction. If pain was so acute as to need anaesthesia for splinting operation was indicated. When the acute symptoms subsided active exercises and heat were beneficial. Manipulative surgery was of no value unless the shoulder had lost its full range of movement.

The symptoms of *osteo-arthritis* might develop insidiously, but often followed over-use of the arm. There was a dull ache in the arm, stiffness of the shoulder, and pain on movement; a diffuse slight tenderness, a little wasting of the muscles, and limitation of all movements, which were painful at their extremes only. Pathogenesis and treatment were the same as for *osteo-arthritis* elsewhere. Physiotherapy was valuable, especially heat and graduated faradism to the shoulder muscles, particularly the abductors.

Subacute arthritis might develop insidiously or might follow trauma or over-use. The symptom was pain on all active or passive movements, but there was little discomfort at rest. The muscles went into spasm and the humerus and scapula moved as one; therefore rotation was more painful than abduction. Radiograms revealed bone atrophy. Many patients were benefited by removal of septic foci. The joint should be rested, preferably in abduction, until muscle spasm disappeared and the patient could lift the arm from the splint. Active movements and faradism should be encouraged as soon as the patient allowed.

Discussion.

Mr. ALAN TODD described an investigation into 52 cases of dislocated shoulder, which had shown that treatment by abduction gave much better end-results and a much quicker recovery than binding the arm to the side. In no case had there been recurrence. The rent was on the inferior aspect of the capsule, and abduction brought the edges into the best possible apposition. The results of binding the arm to the side were disastrous. Applying this result to other shoulder injuries, he argued for their abduction treatment. Inability to abduct the arm beyond the horizontal was the commonest sequel of even minor injuries to the shoulder in people over 50; this meant incapacity for work at most trades. Results of treatment were very unsatisfactory in these people; their adhesions should never be allowed to form. Even coarse grating did not always mean *osteo-arthritis*; it might be intra- or sub-muscular. Elderly people who developed *osteo-arthritis* after an injury were usually those who had had a mild injury.

Dr. A. MERCER described 844 cases of stiff shoulder seen by him as surgeon to an insurance company. Only 93 had recovered within three months; 379 ended in partial and 99 in total permanent incapacity. Nearly all of them had been treated at general hospitals. The patient's resistance was greatest just after the accident, when drastic measures were most likely to succeed. Too often the feelings of the patient were considered and early treatment was too mild or too gradual. It should begin by fixation in abduction, combined with external rotation, followed by gentle movements as soon as pain allowed. The discomfort of the position was a detail compared with the discomfort of adhesions later.

Mr. J. R. LEE said that the shoulder was a muscularly strong joint and almost all its muscles were tendinous, the deltoid particularly having many long tendinous intersections. To this was due the persistence of pain, for tendon was ill-supplied with blood and healed less easily. The large cul-de-sac below the glenoid cavity was bound to have adhesions in it if the arm were put up in adduction. He always adopted Mr. Todd's method, and was sure that these shoulder cases should not be left to house surgeons. He described several cases, illustrating his belief that

that there was more outpouring of blood than was usually recognised.

Mr. B. W. HOWELL described cases of sub-deltoid "bursitis" in one of which calcareous plaques had been seen by X ray but there was no inflammation of the bursa, while in the other there was a bursitis. Operation had cured both. Pain along the bicipital groove might be caused by inflammation of the sub-scapularis tendon, and was best treated by manipulation and hyperextension. Pain immediately after trauma was due to bruising of the glenoid cartilage; later pain came from immobilisation of the shoulder in the course of treatment. He did not like nitrous oxide for manipulation because complete muscular relaxation was not obtained.

Mr. McCRAE AITKIN pointed out that the shoulder stiff from disuse was quite different from the painful shoulder. He deprecated the word "tendonitis"; "tenosynovitis" covered both this condition and the calcareous plaques. The acromio-clavicular joint and its meniscus was subject to curious pains, and might have ætiological significance. He described a case of pain associated with spiculation about a torn origin of the deltoid, and suggested that this might occur in other situations. Painful shoulder might start a few weeks after an injury—such as Colles' fracture—from contusion of cartilage; not until new vascularisation crept in could the joint become painful. The treatment was absolute rest until the disability disappeared. Most cases of painful shoulder could be treated by rest and painless voluntary movement from the start.

Dr. J. F. BRALSFORD reviewed 347 radiographs of painful shoulders; 177 of them had been normal radiologically. Seventy-five had had arthritic changes; 29 had been tuberculous, while 35 had had old undiagnosed fractures (usually of the greater tuberosity) or loose bodies. The commonest lesion was arthritis of the acromio-clavicular joint, usually shown by irregularity of the articular margins. Calcified cysticerci or trichina might cause shoulder disability.

Mr. ROWLEY BRISTOW said that Mr. Mercer's figures were terrible and of paramount importance; this high incidence of incapacity ought to be ventilated.

Dr. S. S. BARTON said that general practitioners met many cases of painful shoulder which never got to the surgeon; they were acute inflammations of the fibrous and tendinous intersections in the muscles, and were cured in a few days by mustard plaster or salicylates in large doses. Another type of case was neuritis, causing muscle wasting; these recovered under electrical treatment.

The PRESIDENT showed two radiographs from patients with pain in the shoulder. One was a woman of 37 who had had occasional violent pains in the shoulder for 26 years, dating from three years after a fall. The left shoulder-girdle and arm were wasted. The attacks had increased in frequency until she was having them every three or four hours. X rays showed a small foreign body between the clavicle and the scapula, and its removal gave complete relief. The second patient had fallen 11 months earlier and had developed persistent pain in the shoulder. X ray revealed dislocation of the cervical spine. Painful shoulders were the great bugbear of the orthopaedic surgeon; treatment must depend on diagnosis. It was important to know if the patient could lie on the shoulder—if so inflammation was not present; also if movement were gradually improving—if so recovery would be aided by forcing movement. He believed that subacute arthritis was the commonest cause and that it was often toxic in origin. Only those who could lie comfortably on the shoulder and had only some of their movements limited were relieved by breaking down adhesions. Operation was the only treatment for acute pain due to calcareous deposits. It was possible to have fluid in the sub-deltoid bursa in cases of shoulder pain; these cases recovered with rest, but operation might hasten their recovery.

Mr. PERKINS, in reply, emphasised that his second group was not one of tenosynovitis, because there was no sheath over the insertion of the supraspinatus muscle.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1927 statistics of two English cities and three English towns, all of county borough status:—

Name of town and estimated (R.G.) population.	Birth-rate.	Death-rates per 1000 of the population.						Death-rates per 1000 births.	
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Diarrhoea, &c., under 2 years.	Maternal mortality from childbirth.
Liverpool (856,266)	22.2	13.9	1.38	1.14	3.6	1.1	94.31	18.4	4.4
Birkenhead (158,500)	18.2	12.6	1.28	1.34	2.5	1.7	95.35	21.9	2.1
Preston (127,100)	14.9	14.0	0.97	1.31	3.4	2.0	109.46	5.8	4.7
Norwich (124,000)	17.1	12.2	1.08	1.53	2.1	1.5	63.29	5.6	1.4
Rotherham (70,050)	20.8	13.5	1.17	1.21	3.2	1.3	90.36	6.8	2.7

The young child (1-5) mortality-rate per 1000 births was: Liverpool, 63; Birkenhead, 57; Preston, 64; Norwich, 36; and Rotherham, 68.

Liverpool.

Dr. A. A. Mussen reports that the infant mortality-rate (94) was the lowest yet recorded, and that the prevalence of influenza, which caused such a large number of deaths among adults, did not apparently affect the infants to any serious extent. There were 350 deaths of children under 2 years from diarrhoea and enteritis, and a special investigation into this subject is described. About three-quarters of these deaths are of the acute infective disease, which is steadily falling, leaving a residuum of deaths where the fatal result is due to other causes. The infective disease chiefly affects the central portion of the city, and in nearly half of the fatal cases the child is found to be definitely unhealthy or suffering from lack of parental care before the onset of diarrhoea. Over 80 per cent. of the deaths from diarrhoea and enteritis occur in the first year of life, and breast-feeding is a real protection against the disease. The death-rate from tuberculosis, although high, was the lowest ever recorded in Liverpool. A striking feature of the statistics is the increasing number of deaths and births which take place in institutions. Thus out of a total of 11,874 deaths of Liverpool residents, 5240 took place in public institutions; and during 1927 3523 of the 19,020 births took place in institutions, whilst in 1923 the corresponding figures were 2138 out of a total of 20,695.

The difficulties with regard to housing are still considerable. No closing orders were made during the years 1922 to 1927 (inclusive). Letters were addressed to the owners of 900 scattered insanitary houses, asking for their proposals thereto. Replies were received, but no definite action has been taken owing to the difficulty of providing accommodation for the dislodged. Nine condemned areas are waiting to be dealt with. A central area scheme, covering about 5.6 acres—involving 2876 inhabitants and 454 dwellings—is under the consideration of the Ministry. It is proposed to provide five blocks, including 408 dwellings, 28 with one bedroom, 95 with two bedrooms, and 285 with three bedrooms, at a total estimated cost of £221,500. Up to the present the corporation have provided, since 1869, 3901 tenements in the old city area; and since 1919 they have erected in the suburbs 15,748 houses and 169 flats, while 1257 other houses are in progress. The rentals of the corporation

tenements vary from 2s. 8½d. to 12s. 6d., and of the self-contained cottages from 8s. 11½d. to 10s. 7½d. per week.

There were eight confirmed cases of anthrax and one death among workers who handled foreign wool, hair, or hides. Sixty-nine new cases of encephalitis were reported with 16 deaths. Nine additional deaths occurred of persons notified in previous years. The death-rate from respiratory diseases, including influenza, which has always been high in Liverpool, during the last seven years was only two-thirds of what it was in 1871 to 1900.

Liverpool has 25 prematernity clinics held weekly, 14 under the auspices of the Maternity Hospital, two at the Royal Infirmary, two by the Child Welfare Association, and seven by the Health Committee. The last-named were attended by 2288 new cases. The wards of the Carnegie centre admitted 109 babies, 43 for lack of normal progress, 20 for infantile dyspepsia, 14 for early rickets, and 32 for observation. Six babies were supervised for breast-feeding, the mothers attending at stated intervals during the day. On five occasions the milk supplied to the hospitals for cooking was found to be tuberculous, and on one occasion the milk supplied to the infant welfare centres. Since Jan. 1st, 1928, the infant welfare centres have been supplied with Grade A (T.T.) milk.

The seamen's V.D. dispensary, with a whole-time medical officer, is much appreciated, and the new V.D. cases there have increased from 1077 in 1925 to 1547 in 1927.

Birkenhead.

Dr. D. Morley Mathieson reports that before the Extension Bill Birkenhead had a density per acre of 37.2, and that only ten of the 82 county boroughs of England and Wales had higher densities at the last census. The Bill operates from April 1st, 1928, and adds 2092 acres, on the western fringe, with a population of 2754. The rainfall at Bidston was about 71 in. above the average of the last 61 years. Of 33 samples of milk examined for tubercle, seven gave a positive result. All the samples were ordinary milk, except one Grade A., the circumstances of which were interesting. A calf, killed at the abattoir, had extensive tuberculosis, and was ascertained to be from an outside farm supplying Grade A milk. On following up it was found that of 77 cows on the farm one had tuberculosis of the udder and another pulmonary tuberculosis, thus indicating that quarterly inspection by a veterinary surgeon is not an absolute safeguard. In the case of the other tuberculous milk samples a tuberculous cow on the farm was found in every case but one. In 15 cases proceedings were taken against vendors of dirty milk, and in all cases successfully.

At the end of the year there were 2080 cases on the tuberculosis register, more than ten times the average number of annual deaths. Of 398 contacts examined five were found to be suffering from respiratory and two from "other" tuberculosis, while 21 were classed as "suspect." Artificial sunlight has been introduced at Thingwall Sanatorium. Dr. Mathieson reports: "On the whole our experience has been that artificial sunlight, judiciously and carefully employed, has proved its worth. But it must not be thought to compare in efficacy with natural sunlight." At the V.D. clinics 100 per cent. increase in the new female gonorrhoea cases is regarded as a satisfactory feature. There were seven cases of encephalitis lethargica notified, five of which ended fatally. Immunisation against diphtheria is offered at the infant welfare clinics, and at the end of the year 176 children had received the full course. The staff at the hospital and patients suffering from other diseases are immunised against diphtheria. A child admitted during 1927 with severe diphtheria was one for whom immunisation was refused in the previous year. The antenatal clinic was attended by 85 women in their first pregnancy and by 300 in a second or subsequent pregnancy. A satisfactory feature was the increased attendance of primigravidae. The total births numbered 2879.

Owing to financial stringency, the dental scheme has hitherto been confined to following up the 6- and 7-year olds, but a second dentist was appointed in November and the scheme will be enlarged. Out of 24,000 elementary scholars 6608 were inspected in 1927; 4166 needed treatment, and 59 per cent. requested to be treated at the dental clinic. Among the school service needs mentioned are classes for partially blind children, an open-air school and hospital treatment for cases of nose and throat obstruction. Owing to the difficulty in using X rays for ringworm in very young children, internal treatment by thallium acetate has been tried. The four children, aged from 2 to 4 years, treated by this method were completely cured.

Preston.

Dr. F. A. Sharpe states that the antenatal work gives promise of success. The new patients at the municipal clinic during the last three years numbered 73, 163, and 272 respectively. About 20 per cent. of the births occur in maternity homes, and at each of the two principal ones there is a carefully organised (non-municipal) antenatal centre. The outstanding need is the co-ordination of the branches of the public health service so that one health visitor may perform all the district visiting in her particular area. Employment was much better in Preston during 1927. Better control is needed for the houses-let-in-lodgings, which include 156 tenancies and house 430 persons. The same comment applies to the 50 permanent vans, housing 124 persons, some of which are arranged in colonies or camps. Of 325 milk samples examined for tubercle 18 gave a positive result. There are only ten cow-keepers in the borough, producing 354 gallons of milk daily. Among these "inside" milch cows two cases of tubercle of the udder and two of other forms were found, and dealt with under the Order.

Influenza was very severe in January and February, and the deaths attributed to it numbered 102. The insurance scheme, by which mothers, when booking midwives, secure medical aid if needed, is on a small scale as yet, but is proving expensive because the doctors are called in to 57.7 per cent. of the cases.

Norwich.

Dr. V. F. Soothill reports that there is a little less unemployment, but that the distress of the last two or three years has necessitated an increased issue of free meals and milk for mothers and children. Some progress has been made with respect to housing. During 1927, 1115 houses were built, including 843 municipal. This makes a total of 3111 new houses since 1918, including those erected for the dishoused inhabitants of slums. Fewer cases of overcrowding are being reported; and progress is being made with three insanitary areas. Dr. Soothill puts in a strong plea for a certain proportion of the council houses with less than three bedrooms. The old houses of Norwich are frequently unsuitable for reconditioning, as they are worn out and badly arranged. The municipal maternity home admitted 223 women for confinement, and its antenatal clinic was attended by 448 expectant mothers. Of 100 samples of milk examined biologically for tubercle one gave a positive result, and the offending cow was traced and destroyed. Uncomplicated cases of scarlet fever are discharged from hospital after four weeks. There were ten notifications of encephalitis lethargica and five deaths. No case of diphtheria has occurred among the hospital staff since immunisation was introduced in November, 1924.

Rotherham.

Dr. W. Barr reports a year of progress. The smoke nuisance is being faced, and the Sheffield and Rotherham Statutory Smoke Abatement Committee is now a going concern. Accommodation for the mentally deficient is rapidly attaining a practical aspect. An orthopaedic scheme for children under 5 years is to be linked up with the school medical service. A new maternity and child welfare centre has been opened, and needs ultra-violet apparatus

in view of the prevalence of rickets in Rotherham. Other needs are X ray apparatus for the sanatorium and dental treatment for expectant mothers and tuberculous patients. The number of new houses in 1927 was 322, including 260 municipal. Some small improvements have been made in the slums. Dr. Barr draws special attention to the difficulty in getting houses renovated owing to the tenants being in arrears with their rent, and gives many instances of this hardship to owners. There are 30 registered cow-keepers in the borough, and ten milch cows were slaughtered under the Tuberculosis Order. Twenty-seven cases of small-pox were reported with no deaths. Diphtheria became prevalent during the later months of the year. There were 104 cases notified and 17 deaths. The epidemic was associated with three schools in turn. Swabbing was adopted for suspicious children, and the virulence test was found useful. Out of 48 carriers of diphtheroid germs four were found to be harbouring a virulent type. Three were cases of ear discharge, and one a school teacher who was absolutely well. Syringing and gargling with a concentrated solution of magnesium sulphate were thought to be useful in drying up the ear discharge and shortening the carrier stage.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED

NOV. 24TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 199 (last week 162); scarlet fever, 2766; diphtheria, 1390; enteric fever, 45; pneumonia, 1092; puerperal fever, 52; puerperal pyrexia, 111; cerebro-spinal fever, 3; acute poliomyelitis, 13; acute poliomyelitis, 2; encephalitis lethargica, 25; dysentery, 19; ophthalmia neonatorum, 93. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified in the following 18 counties:—London, 5; Chester, 7 (Ellesmere Port and Whithby); Derby, 25; Durham, 31 (of these Jarrow 21); Essex, 4 (West Ham); Lancaster, 23 (of these Mossley 15); Leicester, 11 (county borough 9); Lincoln, Parts of Holland 1, Parts of Kesteven 1; Northumberland, 4 (Newcastle-on-Tyne, Tynemouth, 2 each); Nottingham 5; Peterborough, 4 (county borough); Stafford, 11; Wilts, 11 (Swindon 5, Highworth R.D. 6); Yorks, East Riding 1 (Hull), West Riding 31 (Halifax 17; Pontefract, 5); Glamorgan, 13; Monmouth, 11.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Nov. 27th-28th was as follows: Small-pox, under treatment 18, under observation 4; scarlet fever, 2624; diphtheria, 2093; enteric fever, 18; measles, 76; whooping-cough, 332; puerperal fever, 17 (plus 9 babies); encephalitis lethargica, 73; poliomyelitis, 4; "other diseases," 18. At St. Margaret's Hospital there were 10 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox (there was no death from small-pox in the returns for the month of October from areas other than the 107 county boroughs and great towns), no death from enteric fever, 15 (0) from measles, 5 (1) from scarlet fever, 28 (4) from whooping-cough, 34 (5) from diphtheria, 61 (9) from diarrhoea and enteritis under two years, and 49 (9) from influenza. The figures in parentheses are those for London itself.

Stockton-on-Tees reported 3 fatal cases of measles. Liverpool, Hull, and Sunderland 2 each. There were 4 fatal cases of whooping-cough at Liverpool and 3 at Manchester. Diphtheria accounted for 3 fatal cases at Manchester, and diarrhoea for 8 fatal cases at Liverpool, 7 at Manchester, 5 at Salford, and 3 each at Leeds and Middlesbrough, while the figures for the same week for Glasgow, Dublin, and Belfast were 6, 2, and 2 respectively. Influenza claimed no more than 2 deaths in any town.

The number of stillbirths registered during the week in the great towns was 260 (corresponding to a rate of 43 per 1000 births), including 49 in London.

Reviews and Notices of Books.

ANATOMY.

Pocket Atlas of Anatomy. By VICTOR PAUCHET and S. DUPRET. London: Humphrey Milford. Oxford University Press. 1928. Pp. 306. 297 plates. 12s. 6d.

Dr. Pauchet and Mr. Dupret are associated with the Medical School at Amiens, where the former taught anatomy and operative surgery, while the latter exercised effectively his powers as an anatomical artist. In conjunction with Mr. Gaston Doin they have produced a charming little work which Mr. Humphrey Milford now brings before the medical public in this country. The book provides something new. The long list of atlases, previously published, from Joannes Ketam to the latest issue of Carl Toldt, includes no "pocket" atlases; but this one will go into any pocket save that of a waistcoat. There is no text except the labels which are placed on the drawings, and there are no legends, but only titles. The drawings are dainty and exquisitely done. They are clear in spite of their size. All the important points in each figure are labelled, and, where necessary, measurements are given. After working through the skeleton and joints, the authors depict the body, treated in a more regional manner, and finally some 20 plates are devoted to schematic representations of lymphatic distributions. Altogether this is a work which will be greatly appreciated by students of all sorts and will doubtless soon be in common use among them. The authors go so far as to express the hope that it will be in the pockets of those going in for examinations, but they do not suggest any means of dealing with the situation if it should be found there. However, this may be one of the things they manage better in France. The old terminology is used, but, for those who have a liking for foreign tongues, the B.N.A. is added in brackets.

A Shorter Anatomy. By E. WOLFF, M.B., B.S., F.R.C.S. London: H. K. Lewis and Co., Ltd. 1928. Pp. 151. 18s.

This book is intended mainly for those who are revising their anatomical knowledge for their final examinations, but it will also be found useful by more junior students. The medical and surgical application of points described is given at intervals throughout the book, which is an eminently readable little work. Wherever we have tested it it has not failed to give us accurate information in a simple and lucid way. The illustrations are clear and show diagrammatically what they are meant to show. A good feature is a chapter, with X ray photographs, dealing with epiphyses. The book is well produced in easily readable type.

Surface Anatomy. By ARTHUR ROBINSON, M.D., F.R.C.S., Professor of Anatomy; and E. B. JAMIESON, Lecturer on Anatomy in the University of Edinburgh. London: Humphrey Milford. Oxford University Press. 1928. Pp. 175. 15s.

THE names of the authors of this book are sufficient guarantee of the accuracy and value of its contents. It is not a collection of surface-markings, but a true surface "anatomy," in the sense that the reader is made to appreciate how much of his dissecting-room anatomy can be recalled to him from a study of the surface of the living body, by the use of his eyes and hands. This is the proper way to learn and apply anatomy; the work is indeed full of matter which can be read with pleasure and profit by teacher as well as by student. Much information is here given which is not usually supplied in text-books—for instance, the points of entry of muscular nerves. The figures are excellent, though perhaps rather small. An admirable book, which will take its place as a standard work on surface anatomy.

PHARMACOLOGY.

A Text-book of Pharmacology and Therapeutics; or The Action of Drugs in Health and Disease. Ninth edition. By ARTHUR R. CUSHNY, M.A., M.D., LL.D., F.R.S., late Professor of Materia Medica and Pharmacology in the University of Edinburgh. Revised by C. W. EDMUNDS, A.B., M.D., Professor of Materia Medica and Therapeutics in the University of Michigan; and J. A. GUNN, M.A., M.D., D.Sc., Professor of Pharmacology in the University of Oxford. London: J. and A. Churchill. 1928. Pp. 743. 24s.

AT the conclusion of the preface to the eighth edition of his book Prof. Cushny quoted the farewell verse of "The Schoole of Salerne," "And here I cease to write. . . ." Perhaps at that time he contemplated withdrawing from the task of revising this text-book, successive editions of which have for a quarter of a century played a great part in advancing the knowledge of pharmacology. In any case, the words were prophetic, for since the appearance of that edition we have had to deplore his death.

The task of keeping a text-book alive when the author is dead is not easy. It is even more difficult when he has imbued its pages with a strong personality. But Prof. Edmunds and Prof. Gunn have undertaken the work of revision in a pious spirit, and have successfully maintained the personal and critical outlook which was a valued feature of the work. While the immediate object of this version has been to bring it into line with the tenth edition of the United States Pharmacopoeia, each chapter has been revised in the light of the numerous advances of the last few years, and the bibliography has been extended to include all recent important communications. Cushny's "Pharmacology" has been to a generation of students the standard work in the English language, and in its ninth edition should retain its place in popular estimation.

An Introduction to Experimental Pharmacology. By TORALD SOLLMANN, M.D., Professor of Pharmacology and Materia Medica at Western Reserve University, Cleveland, Ohio; and PAUL J. HANZLIK, M.D., Professor of Pharmacology at Stanford University, San Francisco. London and Philadelphia: W. B. Saunders Company. 1928. Pp. 321. 20s.

Prof. Sollmann's "Laboratory Guide in Pharmacology," published in 1917, is recognised by working pharmacologists as one of the most useful books of its class. But, from the point of view of the student, it presented certain disadvantages, particularly in the number, complexity, and meagre explanatory discussion of the experiments. Prof. Sollmann has accordingly, in collaboration with Prof. Hanzlik, adapted his previous work to a more definite course of exercises, reduced the number of experiments, and especially in the exercises on animals has expanded the explanations. The authors obviously share a common experience of laboratory teachers—that the more elaborate the experiments set to be performed by students in training the less likely are they to grasp the essential meaning of their practical work. They have, therefore, laid greater emphasis on demonstrations of the more complex experiments on animals, and there can be no doubt that the advantages of this policy greatly outweigh the sacrifice of personal contact.

The first part of the work is devoted to chemical pharmacology, which besides dealing with plant constituents, pharmaceutical preparations, and the subjects of incompatibility, metrology, and prescription writing, contains chapters on the tests for important drugs, chemical antidotes, antiseptics, and the excretion of drugs by man. It deals also in a most interesting way with the more complex problems of absorption and excretion, osmotic and colloidal phenomena, hemolysis, and agglutination. Practically

Owing to financial stringency, the dental scheme has hitherto been confined to following up the 6- and 7-year olds, but a second dentist was appointed in November and the scheme will be enlarged. Out of 24,000 elementary scholars 6608 were inspected in 1927; 4166 needed treatment, and 59 per cent. requested to be treated at the dental clinic. Among the school service needs mentioned are classes for partially blind children, an open-air school and hospital treatment for cases of nose and throat obstruction. Owing to the difficulty in using X rays for ringworm in very young children, internal treatment by thallium acetate has been tried. The four children, aged from 2 to 4 years, treated by this method were completely cured.

Preston.

Dr. F. A. Sharpe states that the antenatal work gives promise of success. The new patients at the municipal clinic during the last three years numbered 73, 163, and 272 respectively. About 20 per cent. of the births occur in maternity homes, and at each of the two principal ones there is a carefully organised (non-municipal) antenatal centre. The outstanding need is the coördination of the branches of the public health service so that one health visitor may perform all the district visiting in her particular area. Employment was much better in Preston during 1927. Better control is needed for the houses-let-in-lodgings, which include 156 tenancies and house 430 persons. The same comment applies to the 50 permanent vans, housing 124 persons, some of which are arranged in colonies or camps. Of 325 milk samples examined for tubercle 18 gave a positive result. There are only ten cow-keepers in the borough, producing 354 gallons of milk daily. Among these "inside" milch cows two cases of tubercle of the udder and two of other forms were found, and dealt with under the Order.

Influenza was very severe in January and February, and the deaths attributed to it numbered 102. The insurance scheme, by which mothers, when booking midwives, secure medical aid if needed, is on a small scale as yet, but is proving expensive because the doctors are called in to 57.7 per cent. of the cases.

Norwich.

Dr. V. F. Soothill reports that there is a little less unemployment, but that the distress of the last two or three years has necessitated an increased issue of free meals and milk for mothers and children. Some progress has been made with respect to housing. During 1927, 1115 houses were built, including 843 municipal. This makes a total of 3111 new houses since 1918, including those erected for the dishoused inhabitants of slums. Fewer cases of overcrowding are being reported; and progress is being made with three insanitary areas. Dr. Soothill puts in a strong plea for a certain proportion of the council houses with less than three bedrooms. The old houses of Norwich are frequently unsuitable for reconditioning, as they are worn out and badly arranged. The municipal maternity home admitted 223 women for confinement, and its antenatal clinic was attended by 448 expectant mothers. Of 100 samples of milk examined biologically for tubercle one gave a positive result, and the offending cow was traced and destroyed. Uncomplicated cases of scarlet fever are discharged from hospital after four weeks. There were ten notifications of encephalitis lethargica and five deaths. No case of diphtheria has occurred among the hospital staff since immunisation was introduced in November, 1924.

Rotherham.

Dr. W. Barr reports a year of progress. The smoke nuisance is being faced, and the Sheffield and Rotherham Statutory Smoke Abatement Committee is now a going concern. Accommodation for the mentally deficient is rapidly attaining a practical aspect. An orthopaedic scheme for children under 5 years is to be linked up with the school medical service. A new maternity and child welfare centre has been opened, and needs ultra-violet apparatus

in view of the prevalence of rickets in Rotherham. Other needs are X ray apparatus for the sanatorium and dental treatment for expectant mothers and tuberculous patients. The number of new houses in 1927 was 322, including 260 municipal. Some small improvements have been made in the slums. Dr. Barr draws special attention to the difficulty in getting houses renovated owing to the tenants being in arrears with their rent, and gives many instances of this hardship to owners. There are 30 registered cow-keepers in the borough, and ten milch cows were slaughtered under the Tuberculosis Order. Twenty-seven cases of small-pox were reported with no deaths. Diphtheria became prevalent during the later months of the year. There were 104 cases notified and 17 deaths. The epidemic was associated with three schools in turn. Swabbing was adopted for suspicious children, and the virulence test was found useful. Out of 48 carriers of diphtheroid germs four were found to be harbouring a virulent type. Three were cases of ear discharge, and one a school teacher who was absolutely well. Syringing and gargling with a concentrated solution of magnesium sulphate were thought to be useful in drying up the ear discharge and shortening the carrier stage.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED NOV. 24TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 199 (last week 162); scarlet fever, 2766; diphtheria, 1390; enteric fever, 45; pneumonia, 1092; puerperal fever, 52; puerperal pyrexia, 111; cerebro-spinal fever, 3; acute poliomyelitis, 13; acute poliomyelitis, 2; encephalitis lethargica, 25; dysentery, 19; ophthalmia neonatorum, 93. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified in the following 18 counties:—London, 5; Chester, 7 (Ellesmere Port and Whitby); Derby, 25; Durham, 31 (of these Jarrow 24); Essex, 4 (West Ham); Lancaster, 23 (of these Mossley 15); Leicester, 11 (county borough 9); Lincoln, Parts of Holland 1, Parts of Kesteven 1; Northumberland, 4 (Newcastle-on-Tyne, Tynemouth, 2 each); Nottingham 5; Peterborough, 4 (county borough); Stafford, 11; Wilts, 11 (Swindon 5, Highworth R.D. 8); Yorks, East Riding 1 (Hull), West Riding 31 (Halifax 17; Pontefract, 5); Glamorgan, 13; Monmouth, 11.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Nov. 27th-28th was as follows: Small-pox, under treatment 18, under observation 4; scarlet fever, 2624; diphtheria, 2093; enteric fever, 18; measles, 76; whooping-cough, 332; puerperal fever, 17 (plus 9 babies); encephalitis lethargica, 73; poliomyelitis, 4; "other diseases," 18. At St. Margaret's Hospital there were 10 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox (there was no death from small-pox in the returns for the month of October from areas other than the 107 county boroughs and great towns), no death from enteric fever, 15 (0) from measles, 5 (1) from scarlet fever, 28 (4) from whooping-cough, 31 (5) from diphtheria, 61 (9) from diarrhoea and enteritis under two years, and 49 (9) from influenza. The figures in parentheses are those for London itself.

Stockton-on-Tees reported 3 fatal cases of measles. Liverpool, Hull, and Sunderland 2 each. There were 4 fatal cases of whooping-cough at Liverpool and 3 at Manchester. Diphtheria accounted for 3 fatal cases at Manchester, and diarrhoea for 8 fatal cases at Manchester, while 5 at Salford, and 3 each at Leec and the figures for the same week and Belfast were 6, 2, and 2 respectively. Influenza claimed no more than 2 deaths in any town.

The number of stillbirths registered during the week in the great towns was 260 (corresponding to a rate of 43 per 1000 births), including 49 in London.

Reviews and Notices of Books.

ANATOMY.

Pocket Atlas of Anatomy. By VICTOR PAUCHET and S. DUPRET. London: Humphrey Milford, Oxford University Press. 1928. Pp. 306. 297 plates. 12s. 6d.

Dr. Pauchet and Mr. Dupret are associated with the Medical School at Amiens, where the former taught anatomy and operative surgery, while the latter exercised effectively his powers as an anatomical artist. In conjunction with Mr. Gaston Doin they have produced a charming little work which Mr. Humphrey Milford now brings before the medical public in this country. The book provides something new. The long list of atlases, previously published, from Joannes Ketam to the latest issue of Carl Toldt, includes no "pocket" atlases; but this one will go into any pocket save that of a waistcoat. There is no text except the labels which are placed on the drawings, and there are no legends, but only titles. The drawings are dainty and exquisitely done. They are clear in spite of their size. All the important points in each figure are labelled, and, where necessary, measurements are given. After working through the skeleton and joints, the authors depict the body, treated in a more regional manner, and finally some 20 plates are devoted to schematic representations of lymphatic distributions. Altogether this is a work which will be greatly appreciated by students of all sorts and will doubtless soon be in common use among them. The authors go so far as to express the hope that it will be in the pockets of those going in for examinations, but they do not suggest any means of dealing with the situation if it should be found there. However, this may be one of the things they manage better in France. The old terminology is used, but, for those who have a liking for foreign tongues, the B.N.A. is added in brackets.

A Shorter Anatomy. By E. WOLFF, M.B., B.S., F.R.C.S. London: H. K. Lewis and Co., Ltd. 1928. Pp. 451. 18s.

This book is intended mainly for those who are revising their anatomical knowledge for their final examinations, but it will also be found useful by more junior students. The medical and surgical application of points described is given at intervals throughout the book, which is an eminently readable little work. Wherever we have tested it it has not failed to give us accurate information in a simple and lucid way. The illustrations are clear and show diagrammatically what they are meant to show. A good feature is a chapter, with X ray photographs, dealing with epiphyses. The book is well produced in easily readable type.

Surface Anatomy. By ARTHUR ROBERTSON, M.D., F.R.C.S., Professor of Anatomy, and E. B. JAMIESON, Lecturer on Anatomy in the University of Edinburgh. London: Humphrey Milford, Oxford University Press. 1928. Pp. 176. 10s.

THE names of the authors of this book are sufficient guarantee of the accuracy and value of its contents. It is not a collection of surface-anatomical facts, but a "surface anatomy" in the sense that the reader is made to appreciate the importance of the surface anatomy can be readily followed by the student of the surface of the living body by the use of the book. This is the point of view of the authors. In surface anatomy, the work is the best of its kind, and can be read with pleasure and profit by the student as well as by the teacher. Much information is given which is not usually supplied in textbooks of anatomy. The figures are excellent, though not particularly large. An admirable book, which will take its place as a standard work on surface anatomy.

PHARMACOLOGY.

A Text-book of Pharmacology and Therapeutics; or The Action of Drugs in Health and Disease. Ninth edition. By ARTHUR R. CUSHNY, M.A., M.D., LL.D., F.R.S., late Professor of Materia Medica and Pharmacology in the University of Edinburgh. Revised by C. W. EDMUNDS, A.B., M.D., Professor of Materia Medica and Therapeutics in the University of Michigan; and J. A. GUNN, M.A., M.D., D.Sc., Professor of Pharmacology in the University of Oxford. London: J. and A. Churchill. 1928. Pp. 743. 24s.

At the conclusion of the preface to the eighth edition of his book Prof. Cushny quoted the farewell verse of "The Schoole of Salerne." "And here I cease to write. . . ." Perhaps at that time he contemplated withdrawing from the task of revising this text-book, successive editions of which have for a quarter of a century played a great part in advancing the knowledge of pharmacology. In any case, the words were prophetic, for since the appearance of that edition we have had to deplore his death.

The task of keeping a text-book alive when the author is dead is not easy. It is even more difficult when he has imbued its pages with a strong personality. But Prof. Edmunds and Prof. Gunn have undertaken the work of revision in a pious spirit, and have successfully maintained the personal and critical outlook which was a valued feature of the work. While the immediate object of this version has been to bring it into line with the tenth edition of the United States Pharmacopoeia, each chapter has been revised in the light of the numerous advances of the last few years, and the bibliography has been extended to include all recent important communications. Cushny's "Pharmacology" has been to a generation of students the standard work in the English language, and in its ninth edition should retain its place in popular estimation.

An Introduction to Experimental Pharmacology. By DONALD SOLLMANN, M.D., Professor of Pharmacology and Materia Medica at Western Reserve University, Cleveland, Ohio; and PAUL J. HARRIS, M.D., Professor of Pharmacology at Stanford University, San Francisco. London and Philadelphia: W. B. Saunders Company. 1928. Pp. 321. 20s.

Prof. Sollmann's "Laboratory Guide to Pharmacology," published in 1917, is remembered by workers in pharmacology as one of the most useful books of its class. But from the point of view of the student it presented certain disadvantages, particularly in the number, complexity, and nature of the experiments of the experiments. Prof. Sollmann and his colleagues in collaboration with Dr. Harris adapted his earlier work to a more modern and practical approach, reduced the number of experiments, especially in the technique of animal experiments, the experiments. The new book is a more practical and concise guide to the student, and is well adapted to the needs of the laboratory. It is a valuable addition to the literature of pharmacology.

The book is written in a clear and concise style, and is well adapted to the needs of the student. It is a valuable addition to the literature of pharmacology, and is well adapted to the needs of the student.

The book is written in a clear and concise style, and is well adapted to the needs of the student. It is a valuable addition to the literature of pharmacology, and is well adapted to the needs of the student.

The book is written in a clear and concise style, and is well adapted to the needs of the student. It is a valuable addition to the literature of pharmacology, and is well adapted to the needs of the student.

all the work in this section of the book can be performed by the student, and is well suited not only to give him a clear idea of the chemical and physico-chemical reactions between drugs and living tissues, but also to make him appreciate the application of those facts in practical medicine. The second part of the book is concerned with experimental pharmacodynamics. Here are described all the usual experiments on intact animals and isolated tissues, while consideration is given to the questions of allergy, oedemas, irritative reactions, and the treatment of poisoning. Among the many valuable features of the book are the appendices, which contain full details regarding the arrangement and equipment of a pharmacological laboratory, operative anaesthesia, the methods of administering drugs to animals, and the doses likely to produce specific effects. Other important information includes the schedule of the courses on pharmacology at the Western Reserve and Stanford Universities. These may well startle medical educationists in this country who may be tempted to regard pharmacology merely as an appendage of physiology, since in the universities mentioned 128 hours are taken up with practical pharmacology alone. This is possibly excessive, but the authors of this book make very clear the importance of pharmacology, and of an intelligent appreciation of the action of remedial agents in the practical problems of therapeutics.

NEUE DEUTSCHE KLINIK.

Handwörterbuch der praktischen Medizin. Vol. I. Edited by Prof. Dr. GEORG KLEMPERER and Prof. Dr. FELIX KLEMPERER, Berlin. Berlin and Vienna: Urban and Schwarzenberg. 1928. Pp. 733. M.40.

THIS work is being produced to replace "Die Deutsche Klinik am Eingang des 20. Jahrhunderts," published in 15 volumes between 1900 and 1907 by E. v. Leyden and F. Klemperer. The present authors propose to show in their book what medicine owes to German science; they disapprove of what they call the outcry for less science and more intuition in medicine. There are 122 collaborators, German, Austrian, and Swiss, including Hans Eppinger, H. W. Maier, O. Minkowski, C. v. Pirquet, H. Schottmüller, C. Seyfarth, and F. Volhard, to mention only a few. The arrangement is alphabetical, and the size of the work when complete can perhaps be guessed when it is realised that the sections beginning with "A" occupy 734 pages, or practically the whole of the first volume. An average section occupies 20 pages and has on its last page perhaps 30 references. Too often, however, no bibliography is appended.

Selecting Angina Pectoris as a typical section we find a history of the condition going back to Heberden and Jenner. Clear clinical descriptions are given of the angina of effort or chronic angina and of the angina of myocardial infarction, which is called after Wenckebach acute angina pectoris. The morbid anatomy is given in detail, emphasis being placed upon calcification of coronary arteries, thrombosis of the left descending branch, and also syphilitic mesaortitis blocking the coronary orifices. Myomalacia cordis, thinning and aneurysm of the ventricular wall, hæmopericardium, and circumscribed fibrous scarring of the myocardium are all described. This is followed by a discussion of the clinical complications and mode of exodus. For ourselves we should have liked to see the theory of the aortic origin of angina dealt with more severely; neither can we agree that sclerosis of the thoracic aorta leads to cardiac hypertrophy. In precautionary treatment diuretin in doses of 1 g. t.d.s. is recommended. The use of nitrites during attacks is discussed. Surgical intervention, which is described at length, includes paravertebral novocaine or alcohol injection to block the rami communicantes C5 to D4. No mention is made of the various electrocardiographic findings in myocardial infarction.

Sections such as that on the eye changes found in neurology will be much appreciated. It is sub-

divided into a large number of parts dealing with papillitis, papilloedema, optic atrophy, lesions of the chiasma, disturbances of the central optic connexions, retinal changes, oculo-motor palsies, anaesthesia of the cornea, paralysis of tear secretion, and pupillary changes.

The printing, paper, and binding of the volume are good, but the coloured illustrations and some of the clinical photographs are less perfect than we are accustomed to expect in contemporary German text-books. If ten or more further volumes are to appear we begin to wonder whether such subjects as alkalosis and acidosis appearing in Volume I. will not require revision before the last volume is completed. By the practitioner and other busy men who cannot keep pace with the literature of subjects in which they are interested this encyclopædic production should be welcomed. It would serve its purpose even better if the editors insisted that each contributor should append a bibliography to his section.

LABORATORY EXPERIMENTS IN PHYSIOLOGY.

By W. D. ZOETHOUT, Ph.D., Professor of Physiology in the Chicago College of Dental Surgery and Normal School of Physical Education. London: Henry Kimpton. 1928. With 102 illustrations. Pp. 251. 10s. 6d.

THIS manual contains a series of experiments carefully selected by an experienced teacher for students in experimental physiology and biochemistry. The working instructions are prefaced by a series of questions with the object of encouraging the student to marshal his theoretical knowledge before proceeding to practical work. The book is well produced and convenient to handle.

THE ESSENTIAL OILS IN THE TREATMENT OF INFECTIONS.

Traitement Biologique des Infections. By Dr. ALBERT JENTZER, ex-Chirurgien en chef du Second Service de Chirurgie à l'Hôpital Cantonal de Genève. Paris: Masson et Cie. 1928. Pp. 424. Fr.80.

THE author of this book claims to have devised a method of treating acute and chronic septic infections which is a great advance on previous practice. For acute infections he uses a preparation of various essential oils and resins which he calls them saline; for chronic infections a similar preparation containing lipoids called lipodéterpénol. A great deal of work is reviewed in the book and there is an exhaustive bibliography at least as far as concerns the literature of the pharmacology of the essential oils. The description of the properties, compositions, toxicity, and therapeutic actions of the various oils occupies 76 pages. An account of them saline follows. Its exact method of preparation is not given but the results of its therapeutic application are fully described. The sole contra-indication to its use recognised by Dr. Jentzer is the presence of a lung infection. The part played by lipoids in immunity, certain facts of allergy, and Besredka's work on the rôle of the skin are there reviewed. These chapters really serve as an introduction to that part of the book which deals with the use of lipodéterpénol. This preparation is administered in association with them saline partly by subcutaneous injection, partly by rubbing it into the skin. Some animal experiments and clinical experiences are cited to prove the efficacy of the method.

It is difficult to form an accurate judgment of the value of the treatment recommended from a perusal of the book. The evidence brought forward is not so striking as might be expected from the claims of the author, and adequate details as to the method of preparing the remedies are lacking. A carefully organised trial of the methods would be necessary if the efficacy of such treatment were to be properly appraised.

THE LANCET.

LONDON: SATURDAY, DECEMBER 8, 1928.

THE KING'S ILLNESS.

THE KING's condition has given cause for grave anxiety throughout the past week. The infection in the lung is of a kind with which medical men have become familiar during the last ten years, and it is not surprising to expect no sudden termination by crisis in any set period of duration. The course often runs in its phases or chapters of infection varying in severity, and the temperature settles slowly and intermittently. A considerable strain on the heart has therefore been involved—the degree of this strain being determined not only by the virulence of the infection but also by the time it lasts. Now that the illness has entered into its third week the clinical picture has become more complete, and as unfounded conjecture is impossible we offer the following information, authorised to say that the essential facts are as follows.

As early as practicable in the illness a blood sample was taken and the result was positive, the infection having been shown to be of a coccidial character. Blood counts have shown a leucocytosis of the polymorphonuclear variety. Radiology has been useful in that clear pictures were obtained, confirming the clinical evidence that the lower two-thirds of the lung was the area involved. There is up to the present time no appreciable pleural effusion, but the pleurisy described in the bulletins unfortunately extended to the diaphragm, causing severe distress which constantly needed mitigation. Attacks of bronchial spasm have from time to time added to the difficulties. It will be recognised how important in such an illness it is to save the patient the anxiety and tear of pain and distress by promoting rest and sleep, and in this task the best of medical art has played no small part. Measures immediately directed against the infection have taken the form of chemical antidote and attempts to raise the temperature and promote leucocytosis. There is reason to think that some control—and perhaps curtailment—has thus been secured. At the time of writing the physical signs in the chest have diminished, the corresponding local symptoms have improved, but, however, still an ebb and flow, and medical men cannot but be told that the strain on the heart in the case of a severe infection lasting over two weeks must be an anxious problem, especially in a patient of over 60 years of age. This strain on the heart and the severity of the general toxæmia are the chief cause of the serious anxiety which has for some days continued.

In an illness which pre-occupies the mind of the English-speaking peoples, and has moved the civilised world, the thoughts of many will turn with sympathy to those responsible for HIS MAJESTY'S care. During these troubled weeks they have included Sir Stanley Hewett, Lord Dawson, Sir Humphry Rolleston, Sir Farquhar Buzzard, Dr. L. E. H. Whitby, Dr. Graham Hodgson, Nurse Purdie (Westminster Hospital), Nurse Black and Nurse Davies (London Hospital), and Nurse Gordon (St. Thomas's Hospital). In our hopes for the KING's recovery the burden of their tasks will not be forgotten.

SURGICAL ACCESS TO THE BRAIN.

THE problem of obtaining easy access to the interior of the skull has become of increasing importance with the modern demand for large openings, into which it shall be possible to replace the bone without fear of risking its vitality. Several questions arise, the first of which is that of access to the skull itself. It is a curious example of the force of tradition that until quite recently it was generally believed that contact with the scalp must be maintained if the blood-supply of a bone flap is to be preserved. In his recent Hunterian lecture, however, Mr. H. S. SOUTTAR made it quite clear that the vascular supply of the bone and the scalp are independent, so that the scalp may be turned down freely without prejudice to the vitality of an osteoplastic flap, which derives its vascular supply entirely from its muscular pedicle. Nothing then stands in the way of that free exposure of the skull which is obviously the first stage towards easy access to the brain. But even when the skull has been freely exposed, the actual division of the bone presents mechanical difficulties of no mean order. With the old methods it involved an expenditure of time and a degree of exertion on the part of the surgeon which only too often left both patient and surgeon physically exhausted, at a moment when the real business of the operation was only about to begin. In recent years this factor in the problem has received much attention, and in an article in our present issue Mr. W. H. OGILVIE describes an ingenious appliance, in which compressed air is used as the motive power to drive a series of drills, saws, and burrs, by means of which the skull may be rapidly opened in any situation. As a source of power compressed air possesses the advantage of being cheap, easily obtained, and sterile, whilst there can be no doubt as to the mechanical efficiency of the tools themselves. The most doubtful link in the operative chain is indeed the surgeon himself, who, oddly enough, is rarely a mechanic, and does not readily adapt himself to new mechanical methods.

In general terms there are three distinct methods by which the skull may be divided. The first can be carried out with the ordinary appliances of the operating theatre, and consists in cutting a series of holes with a drill or trephine along the intended line

all the work in this section of the book can be performed by the student, and is well suited not only to give him a clear idea of the chemical and physico-chemical reactions between drugs and living tissues, but also to make him appreciate the application of those facts in practical medicine. The second part of the book is concerned with experimental pharmacodynamics. Here are described all the usual experiments on intact animals and isolated tissues, while consideration is given to the questions of allergy, œdemas, irritative reactions, and the treatment of poisoning. Among the many valuable features of the book are the appendices, which contain full details regarding the arrangement and equipment of a pharmacological laboratory, operative anaesthesia, the methods of administering drugs to animals, and the doses likely to produce specific effects. Other important information includes the schedule of the courses on pharmacology at the Western Reserve and Stanford Universities. These may well startle medical educationists in this country who may be tempted to regard pharmacology merely as an appendage of physiology, since in the universities mentioned 128 hours are taken up with practical pharmacology alone. This is possibly excessive, but the authors of this book make very clear the importance of pharmacology, and of an intelligent appreciation of the action of remedial agents in the practical problems of therapeutics.

NEUE DEUTSCHE KLINIK.

Handwörterbuch der praktischen Medizin. Vol. I. Edited by Prof. Dr. GEORG KLEMPERER and Prof. Dr. FELIX KLEMPERER, Berlin. Berlin and Vienna: Urban and Schwarzenberg. 1928. Pp. 783. M.40.

THIS work is being produced to replace "Die Deutsche Klinik am Eingang des 20. Jahrhunderts," published in 15 volumes between 1900 and 1907 by E. v. Leyden and F. Klemperer. The present authors propose to show in their book what medicine owes to German science; they disapprove of what they call the outcry for less science and more intuition in medicine. There are 122 collaborators, German, Austrian, and Swiss, including Hans Eppinger, H. W. Maier, O. Minkowski, C. v. Pirquet, H. Schottmüller, C. Seyfarth, and F. Vollhard, to mention only a few. THE ESSENTIAL OILS IN THE TREATMENT OF INFECTIONS.

Traitement Biologique des Infections. By Dr. ALBERT JENTZER, ex-Chirurgien en chef du Second Service de Chirurgie à l'Hôpital Cantonal de Genève. Paris: Masson et Cie. 1928. Pp. 424. Fr.80.

THE author of this book claims to have devised a method of treating acute and chronic septic infections which is a great advance on previous practice. For acute infections he uses a preparation of various essential oils and resins which he calls themsaline; for chronic infections a similar preparation containing lipoids called lipodéterpénol. A great deal of work is reviewed in the book and there is an exhaustive bibliography at least as far as concerns the literature of the pharmacology of the essential oils. The description of the properties, compositions, toxicity, and therapeutic actions of the various oils occupies 76 pages. An account of themsaline follows. Its exact method of preparation is not given but the results of its therapeutic application are fully described. The sole contra-indication to its use recognised by Dr. Jentzer is the presence of a lung infection. The part played by lipoids in immunity, certain facts of allergy, and Besredka's work on the rôle of the skin are there reviewed. These chapters really serve as an introduction to that part of the book which deals with the use of lipodéterpénol. This preparation is administered in association with themsaline partly by subcutaneous injection, partly by rubbing it into the skin. Some animal experiments and clinical experiences are cited to prove the efficacy of the method.

It is difficult to form an accurate judgment of the value of the treatment recommended from a perusal of the book. The evidence brought forward is not so striking as might be expected from the claims of the author, and adequate details as to the method of preparing the remedies are lacking. A carefully organised trial of the methods would be necessary if the efficacy of such treatment were to be properly appraised.

authorities themselves, if framing assessments unaided, would have behaved with greater sympathy.

Finally, if all else fails, if the hospital is heavily assessed and if all appeal and argument have been in vain, there is yet one possibility left. By virtue of Section 131 of the Public Health Act of 1875 an English local authority can, for the purpose of providing hospital accommodation for its district, enter into agreements with the managers of hospitals. Section 64 of the Public Health Act of 1925 extends this power to include the making of reasonable subscriptions or donations to a voluntary hospital "if the local authority are satisfied that by so doing they will maintain or extend or increase the efficiency of hospital accommodation for the sick inhabitants of the district." The expenditure under this 1925 provision is limited to a penny rate, but it seems that this limit has not been approached. A memorandum attached to Mr. ORR's report estimates that in the past our hospitals have received by way of preferential rating approximately £250,000 per annum, whereas, if they received subscriptions or donations up to the full limit of the penny rate, they would receive approximately a million pounds.

HENRY HILL HICKMAN.

On April 2nd of next year falls the centenary of the death of one who, in his own way, may almost be called a martyr to science. HENRY HILL HICKMAN died at the early age of 30, broken-hearted at his failure to obtain any support for nitrous oxide anaesthesia. He was born in 1800 at Lady Walton, near Bromfield in Shropshire, qualified M.R.C.S. in 1820, and practised at Ludlow. Soon afterwards he began a series of experiments on animals with a view to rendering them unconscious before an operation. He first produced semi-asphyxiation by the exclusion of atmospheric air and next rendered dogs insensible by nitrous oxide and carbonic dioxide gases. While they were unconscious he excised their ears and amputated their legs, and then dressed the wounds and noted the time they took to heal. Encouraged by the success of these experiments, in 1825 he removed to Shifnal and endeavoured to demonstrate the results of his investigations to his medical brethren, but they received his views with derision and condemned them as dangerous and useless. As the medical press refused to publish the results of his experiments he made them known in 1824 in a letter to a sympathetic layman, Mr. T. A. Knight, of Downton Castle, who had them printed as a pamphlet. Unable to experiment, as he hoped, on a human subject in England, he decided to lay the matter before the physicians of France, and with that object he petitioned King Charles X. to be allowed to perform his experiments before the leading medical men in Paris. In his letter he alludes to his "discovery" as one he had "entirely originated" himself, and by means of which he was "able to produce insensibility by the introduction of certain gases into the lungs." The letter was referred to the Royal Academy of Medicine, who considered it at a meeting on Oct. 21st, 1828, and selected Mr. Gréguin to report on the matter. A committee was appointed to consider the subject, and although the announcement of Hickman's discovery caused a sensation it was received with contempt by the members, with the exception of Baron Larrey, who offered himself for the experiment. Nothing further was done in the matter, and it was allowed to drop.

Hickman, who had gone to Paris, was grievously disappointed and died shortly after his return to England.

It was another 30 years before nitrous oxide anaesthesia was taken seriously, and it is amusing to read in THE LANCET of 1868 the reports of meetings and demonstrations and the varied opinions expressed. The seed sown in France by Hickman may have borne some fruit, for it was Dr. T. W. Evans, of Paris, who brought the new anaesthetic to London. 24,000 cases were already on record in America, and to these Dr. Evans added another 1000. He administered gas to 11 patients at the Dental Hospital, Soho-square, on March 31st, to several patients at the house of Mr. Hepburn next day, and to eight more patients at the Dental Hospital on April 2nd. On April 6th Mr. Underwood brought these experiments to the notice of the members of the Odontological Society of Great Britain.¹ So enthusiastic was Dr. Evans that he left the sum of £100 to the Dental Hospital to investigate this anaesthetic, or—if it did not prove satisfactory—any other method of relieving the pain of minor operations. A committee of the society was appointed to investigate the matter, and reported in December² to a crowded meeting. The advantages put forward for nitrous oxide anaesthesia were the rapidity of its action and of the patient's recovery, and there appeared to be no ill-effects and no contra-indications to its use. Its expense, the difficulty of preparing and transporting it and the complicated apparatus necessary for its administration constituted, however, a grave list of objections. Our considered opinion was guarded, but not so gloomy as that of the President of the Medical Society, Dr. B. W. Richardson, who was at pains to assure his audience that nitrous oxide was one of the "best known, least wonderful, and most dangerous of all substances that had been applied for the production of general anaesthesia."³ "The administration of laughing gas," remarked our representative at that meeting, "is becoming a pastime for amateurs," and a most unsuitable pastime he certainly regarded it.

Through all this excitement Hickman was forgotten, and it was not until 1912 that his memory was revived by Mr. C. J. S. Thompson, for many years curator of the Wellcome Historical Medical Museum.⁴ A hundred years too late to save him disappointment and despair, his countrymen seek to do him honour, it is proposed to renew his tombstone, to place a memorial tablet in Bromfield Parish Church, to procure a portrait for the Royal Society of Medicine, and—if funds permit—to establish a Hickman Prize for original work in anaesthesia. The committee consists of Lord Dawson (chairman), Sir St. Clair Thomson (vice-chairman), the Editors of the *British Medical Journal* and *The Lancet*, Dr. Dudley Buxton, Dr. H. R. Spencer, Dr. Z. Menzell, Rev. Prebendary W. Joyce, Mr. C. J. S. Thompson, Mr. Ashley Daly, and the secretaries, Dr. W. J. McCardie and Dr. Cecil Hughes. The fund will remain open until the end of January, and subscribers will then be consulted by the committee on the disposal of the fund. Subscriptions of any amount up to two guineas should be sent to the hon. treasurer, Mr. V. Warren Low, 76, Harley-street, W. 1.

of section, and joining these up by means of a hand saw, a Gigli saw, or some variety of cutting forceps. In the second method a powerful electric motor is used to drill the holes and to join these up by means of a circular saw, or some form of burr such as that used by DE MARTEL. The third consists in the use of an entirely specialised appliance. While the first of these methods has the advantage of simplicity it is necessarily somewhat rough and crude, and it demands from the surgeon a degree of exertion which may spoil his touch for the delicate work to which it is only a prelude. It is, however, the method at present in general use. For the second method many excellent motors are now on the market, in which it is possible to sterilise all the parts with which the surgeon comes in contact, and in which he can control the speed to suit his requirements—two essentials for satisfactory work in this difficult region. Such motors, however, are expensive and cumbersome and will only be found in large institutions, so that the peculiarities of English practice render their use difficult in a surgeon's private work. A portable apparatus, readily sterilised in its entirety, which could be worked by hand without undue exertion, would be a real boon to the surgeon. Such an apparatus has been devised by Mr. SOUTTAR and is now coming into general use. The principle on which it works is the novel one of securing a steel peg in the skull at the centre of the proposed flap and using this as a fulcrum round which can turn a powerful lever carrying a cutting tool. The cutting tool is a narrow chisel such as is used by turners for parting their work, and it cuts in the skull a narrow circular channel with extreme precision. The groove is cut on a bevel, and one advantage of the method is that the bone-flap can be replaced with the accuracy of a ground glass stopper. Naturally, so novel an instrument requires some practice before it can be used with facility, but when this is attained, large bone flaps can be cut with an ease and rapidity hitherto unattained; we have seen a four-inch flap turned down in the temporal region in four minutes without apparent effort on the surgeon's part.

There is no art in which the human factor is more important than in surgery, and it is therefore well that surgeons should have at their disposal a large variety of methods from which to choose. The stock of any instrument-maker will show the efforts that have been made to meet their individual requirements, but we have sometimes wished that surgeons themselves would realise the essentially mechanical nature of some of the problems by which they are faced and the technical skill required to use successfully the elaborate appliances now placed at their disposal. It would be an immense advantage to the student if at some point of his training he were taught something of the mechanic's art, and came to realise the cunning of the hand involved in the dexterous use of even the simplest tool. Whilst we fully recognise the ingenuity of the instruments provided for the surgeons' use, it cannot be disputed that their success must ultimately depend on the skill of the hand which uses them.

THE RATING OF VOLUNTARY HOSPITALS.

THERE was once a time when, for want of an obvious person to be assessed, hospitals were not regarded as rateable. When the law stood thus nobody's sense of justice was offended. In 1875 the House of Lords unfortunately found reasons for holding that rates must be paid on voluntary hospitals as on other premises. This change in the law brought no particular pleasure or profit to anybody. No one

has ever wanted to increase the hospitals' burden, and it is strange that Parliament should never have given them exemption from the rates. To-day, when the Government is planning to relieve productive industry, the chance has arisen to include hospitals in the de-rating proposals. For various reasons the idea may not be officially welcome. After a period of preparation and discussion the de-rating scheme with its complicated finance has finally taken shape; rating relief is concentrated upon industrial undertakings, not upon institutions; the preliminary provisions of the Rating and Valuation (Apportionment) Act, passed last summer, dealt with agricultural, industrial, and freight-transport hereditaments only, and we shall no doubt be told that it is too late to introduce a new kind of property into the carefully planned stages of the de-rating programme. Still we trust that the possibility of bringing the hospitals within the scheme will not be set aside without thorough examination.

If this chance fails there are two other possibilities. In the first place, it should be feasible to standardise the rating of hospitals throughout the country upon the lowest and most sympathetic assessment. It is well known that the principles of rating in England have varied greatly in different areas. A greater measure of uniformity was one of the results expected from the Rating and Valuation Act of 1925. By cutting down the number of assessment authorities the Act reduced the chances of local variation; further, by setting up a Central Valuation Board, it was hoped to bring the different areas into line with one another and to secure the adoption of a common practice in assessing particular kinds of property. The Central Valuation Board has no powers of enforcing its views but is merely an advisory or persuasive body. Its opinions about the rating of voluntary hospitals have been expressed; they are printed in an appendix to Mr. R. H. P. ORDE's Ninth Annual Report (for the year 1927) on the Voluntary Hospitals in Great Britain. The Board suggests that rating and assessment authorities should be reminded of the common basis for decision. The practical question in the assessment of property is its value to the hypothetical tenant: what would be the reasonable annual rent if the property were in the market to be let for the purpose for which it is at present used? As the Board points out, the assessment authority ought to consider certain specific points when examining the case of a voluntary hospital. One point is the purpose for which the property is actually used and its fitness for that purpose. Another is the undoubted fact that rating and assessment authorities have in the past made a practice of taking into account the principle that the present occupiers of a voluntary hospital can be regarded as possible tenants only so long as they are able to rely upon voluntary contributions from the general public to enable them to continue the occupation and use of the property for hospital purposes. A third point for the rating and assessment authorities is the consideration of all the responsibilities, conditions, restrictions, and circumstances under which the voluntary organisation continues in occupation of the property. If these three points are borne in mind a heavy assessment should be out of the question. Assessments have, however, in many areas been most oppressive. It may be that, in tackling the task of general re-assessment and re-rating which was imposed by the Act of 1925, the local authorities placed themselves in the hands of experts who thought only in terms of big figures and who paid too little regard to local institutions towards which the local

with the dairy work and by the occurrence on the farm lands subsequently of two cases of diphtheria in patients who, like so many farm labourers' children, were not consumers of fresh milk. At any rate, the facts of this carefully investigated little outbreak are of great interest as a reminder of a mode of milk contamination which had come to be rather discounted.

THE LETTERS OF JOHN RAY.

THE eighty-fourth year of the Ray Society saw the tercentenary of the birth of its eponym. The 114th volume of the proceedings¹ consists of unpublished letters of Ray, and amplifies the two volumes of life and correspondence issued by the society in 1846 and 1848 under the supervision of the then secretary, Dr. Edwin Lankester. Much information has come to light in the past 80 years, and the society is fortunate in having Mr. Gunther's scholarly work as a memorial of Ray's tercentenary. The present series of letters is the outcome of a rediscovery in the Bodleian Library of a number of Ray's letters, addressed for the most part to Aubrey and Lhwyd. The latter was keeper of the Ashmolean Museum, where, before their transference to the Bodleian, these letters were housed; their presence there appears to have been overlooked by Dr. Lankester. Fourteen letters are addressed to Aubrey and 15 to Lhwyd, the dates being 1690 to 1691. In 1890 the Bodleian acquired a further series of 26 letters from Ray to Lhwyd, of dates between 1689 and 1703. Nine letters dated 1670-1693 in Ray's holograph were found in the letter books of the Royal Society. Of the letters issued by Derham in 1718, mainly addressed to Martin Lister, many were not printed in full; the details of personal interest which were omitted have now been supplied. A chronological table of Ray's letters, published in 1848 and in the present volume, shows well how the gaps in the former volume are bridged by the present one. Of the first 19 letters, all addressed to Peter Courthope of Danny, only four are to be found in the 1848 volume. Two short lives of Ray, by Dale and Petiver, are here abridged, and the uncertainty of the exact date of Ray's birth is satisfactorily settled by a facsimile of the record in the parish register of 1627. Some of the letters in the present series are in Latin, but by far the greater number are in English and are extraordinarily interesting; they enable us to form some estimate of the great naturalist, the rectitude of whose character is proved by his refusal to sign the Solemn League and Covenant, which refusal deprived him of his Fellowship at Trinity College, Cambridge. His thirst for information is brought out strongly, as well as his willingness to impart his special knowledge to others.

Ray gives explicit instructions to his correspondents as to how books, plants, &c., are to be sent to him; over and over again he informs them that the Braintree carrier "comes at the Pewter-Pot, in Leadenhall-street, and comes out of town on Friday mornings weekly." His letters contain many shrewd comments on his contemporaries; of Father Kircher he says: "I account him a credulous person, possessed with ye vanity of most of ye religious of his church who delight to tell strange and miraculous tales to amuse and delude ye vulgar." He gives as a reason for not sending Lhwyd a copy of one of his books, "the bookseller concerned in that copy is so stingy and would not allow me copies to present my friends." In the matter of Dr. Burnet's "Theory of ye earth": "A great deal of stuff he hath about the mystical and allegorical physiology of the solids, which I understand not, nor I believe himself neither." A little further on he says of the same matter, "methinks his book in many places smacks rank of the enthusiast." Some few details of medical interest appear in places. Thus for his

diarrhoea he found "a very easy and pleasant medicine to be Naples-bisket boiled in milk." The lost letters of Ray to Lister and Tancered Robinson, 1683-1704, are here epitomised from Dering and a very complete index, with references to the 1848 and 1928 volumes, completes a work which illustrates well the scientific attitude and breadth of mind of one of the greatest English naturalists of all time.

INJECTION TREATMENT OF VARICOSE VEINS.

ON the whole the operative treatment of varicose veins cannot be said to have given good results. Seldom can a really successful issue be predicted; usually surgery does no more than reduce disability, and in the remaining cases there is little or no improvement. The popularity of the various forms of injection treatment is rapidly relegating operative measures to a position of merely historic importance. Of its immediate success there is no doubt, though time alone will show what permanence may be expected. Like other forms of treatment, it is, of course, not entirely devoid of risks, and something may be learned of these from a paper¹ in which McPheeters and Rice review from the literature and from their own experience the complications which may follow. The accidents formerly associated with the method were due to the employment of coagulant solutions or to lack of aseptic precautions, but now a total of 53,000 cases treated by injection has been recorded in the literature, with but seven deaths. Of these fatalities pulmonary emboli were responsible for four, whilst the remaining patients died from septic thrombophlebitis, mercury poisoning, and septicæmia respectively. Three other fatal cases have also been reported, but in these the issue is obscured by the presence of some other disease which might equally have been responsible for death. When septic thrombophlebitis occurs these writers consider it much more likely to be due to the lighting up of a latent phlebitis than to the introduction of organisms at the time of injection. On their showing the published figures indicate an extremely low mortality from injection treatment—a mortality many times less than that associated with operation. Of the less serious local complications sloughing and sepsis should be avoidable with proper technique, and the danger of thrombosis developing in the deep veins of the limb has been proved more theoretical than real. The new treatment is admittedly in its infancy, but the results have been very encouraging. The technique is comparatively simple, serious complications almost non-existent, and with due care a cure can be effected in nearly every case.

THE RODS AND CONES.
